Summary

The magnetic field contains the dominant energy per unit volume in the solar corona and therefore plays an important role in most coronal phenomena. But until now, no direct measurement of the magnetic field vector distribution in the corona could be made. Models of the coronal magnetic field rely almost entirely on extrapolations of photospheric magnetic field observations. Some indirect information about the coronal magnetic field, however, can be obtained using the Faraday, longitudinal Zeeman or Hanle effects on emissions at magnetically sensitive coronal transition lines. The Faraday and longitudinal Zeeman effects provide the line-of-sight component of the magnetic field integrated over the line-of-sight. Polarimetric measurements of the Hanle effect yields information about the magnetic field orientation integrated along the line of sight.

In this thesis, we investigate whether a tomographic reconstruction based on these observations allow us to obtain a reliable model of the vector magnetic field in the whole solar corona. The inversion problem is strongly ill-posed. To improve the condition of the inversion problem we use the fact that the magnetic field has to satisfy $\nabla \cdot \mathbf{B} = 0$ as an additional regularization constraint. The use of this constraint, however, may require additional solar surface magnetogram data as boundary condition. With the help of this constraint, we show that it is possible to reconstruct both the strength and direction of the magnetic field from the mentioned above observations. The reconstructed field contains details, which cannot be obtained with a traditional extrapolation of the photospheric surface field measurements.

The inversion code based on the effects mentioned above has been developed. The code is tested using simulated data of the longitudinal Zeeman and Hanle effects including some artificial noise. The magnetic field configuration is chosen to consist of two parts: a mean dipole field component and non-potential field component induced by a circular current in the corona. The tomographic inversion of the simulated data allows us to reconstruct the potential and the non-potential component of the field, while a traditional potential field approximation reconstructs only the main dipole field component.

1 Introduction

The corona is the outermost part of the Sun's atmosphere. It is bounded below at ~ 2.5 Mm above the solar surface by the thin (~ 500 km) transition region within which the plasma temperature rises from chromospheric values of below 10^4 K to typical coronal temperatures of above 10^6 K. The solar corona is structured by the coronal magnetic field which is rooted at the solar surface and is partially open to the heliosphere. The outer boundary of the corona is not precisely defined. Its outer boundary may be placed at a distance of $\sim 2-3R_\odot$ above the solar surface where the magnetic field lines are dragged out by the solar wind and bent into radial direction.

The solar corona consists of a hot ($> 10^6$ K), highly ionized and very low density plasma ($\lesssim 10^{10}$ cm $^{-3}$). The highest temperature of the coronal plasma is achieved in regions with closed magnetic field lines where the plasma is confined and cannot escape into the heliosphere. The reason for its high temperature is still uncertain but most explanations for the coronal heating mechanism involve the coronal magnetic field (Zirker 1993; Ulmschneider 1998; Erdelyi 2004).

The bulk motion of the coronal plasma as a fluid is governed by the pressure gradient, gravity and magnetic Lorentz force. The ratio of the first two forces can be expressed by the ratio of the pressure scale height H to a typical length scale L over which the pressure varies. Here, $H = k_B T / m_H g_\odot$ where k_B is the Boltzmann constant, T is the coronal temperature, m_H is the mass of a proton, the dominant ion in the corona, and g_\odot is the Sun's gravitational acceleration. Perpendicular to the field lines, typically $L \ll H \sim 50$ Mm, so that gravity often plays a minor role. The ratio of the pressure force to the Lorentz force $\mathbf{J} \times \mathbf{B}$ is expressed by the parameter $\beta = 2\mu_0 p / B^2$, where p is the thermal pressure, \mathbf{B} is the magnetic field vector, \mathbf{J} is the electric current density vector, and μ_0 is the magnetic permeability. In the inner corona from the chromosphere up to $\sim 1.5R_\odot$, (and sometimes higher) the plasma- β mostly is less than unity (Gary 2001). Therefore, the coronal magnetic field is strong enough to effectively dominate the plasma motion. It can therefore be considered as the main driving force of most plasma phenomena occurring in the inner corona. To understand the physics of the corona, a detailed knowledge of the coronal magnetic field is therefore absolutely essential.

Unfortunately, direct magnetic field measurements in the corona are extremely difficult. The majority of solar magnetic field measurements in the past have been taken in the photosphere. A standard way to estimate the field in the corona is then to extrapolate the radial photospheric magnetic field component using the potential field or more sophisticated model approximations. But the potential field extrapolation does not take into account any electric current in the corona and, therefore, misses an important part of the physics. Since the potential magnetic field is the field with the minimum energy for a given photospheric radial boundary condition (Sakurai 1989), it cannot account for

dynamical processes such as eruptions and flares, where very probably magnetic energy is converted into plasma kinetic energy. Indeed, soft X-ray observations of active regions often show a non-potential structure of the magnetic field (Jiao et al. 1997). Observations of the horizontal surface field by vector magnetographs have been used to estimate radial currents in the photosphere, part of which probably flows along field lines out into the corona (Hagyard & Pevtsov 1999). More realistic models of the coronal field can be obtained by applying the force-free approximation which neglects pressure and gravity forces (Cuperman et al. 1990; Flyer et al. 2004). This method consists in solving a boundary value problem for the equations $(\nabla \times \mathbf{B}) \times \mathbf{B} = 0$ and $\nabla \cdot \mathbf{B} = 0$, using the radial and horizontal magnetic field components measured at the photospheric level as boundary values. The main difficulties here are: the procedure is numerically ill-posed, and the results are less reliable with increasing distance from the surface (Demoulin et al. 1992).

The measurements used for the determination of the line-of-sight (LOS) component of the magnetic field at the photosphere are based on the Zeeman effect. At optical wavelengths this method is not sensitive enough to be used for coronal measurements, because the coronal magnetic field strength (~ 10 G) is relatively small and the temperature ($\sim 10^6$ K) in the corona is very high so that the Zeeman splitting is much smaller than the thermal broadening of the line.

Polarimetric coronagraph observations of coronal emission lines have been used to estimate the orientation of the coronal magnetic field in the plane of the sky (POS) through the Hanle effect for emission lines from forbidden atomic transitions. The possibility of making use of the Hanle effect to derive the coronal magnetic field from the polarimetric measurements was first investigated by Charvin(1965) and was further developed by many authors (House 1974,1977; House et al. 1982; Sahal-Brechot 1974a,b, 1977; Cassini & Judge 1999). An example of such an observations is shown in Fig. 1.1a.

Landi Degl’Innocenti & Landi Degl’Innocenti (1973), Landi Degl’Innocenti (1982) and later Casini & Judge (1999) proposed and investigated the possibility to use spectropolarimetric observations at infrared wavelengths to derive a longitudinal magnetic field estimate in the corona from the longitudinal Zeeman effect. Promising coronagraph measurements of this kind have only recently been achieved for infrared coronal lines (Lin et al. 2000, 2004). Although these measurements were restricted to heights below $0.45R_{\odot}$ above an active region, they demonstrate that the measurement technique has the potential to be applied to the whole corona. Currently, a precision of ± 1 G is obtained with these observations after 70 minutes of integration (for Stokes- V spectrum).

Both the coronal Hanle effect observations and the coronal Zeeman effect measurements are effectively LOS integrations through the corona because the respective coronal lines are optically thin. The measurements are therefore not localized and their interpretation in terms of magnetic flux densities is not straightforward. In the present thesis we want to explore to which extent these data provide sufficient information to allow a reconstruction of the three-dimensional (3D) magnetic field in the corona. It is not clear that the information is sufficient: a 3D vector field locally has three degrees of freedom (i.e., the three vector components), while the Zeeman and Hanle effect observations provide only a single scalar value (the projection of the vector along the LOS integrated over the LOS for the Zeeman effect) or two scalar values (polarization degree and orientation of the polarization plane integrated over the LOS for the Hanle effect).

The inversion of LOS integrated information to a local 3D distribution is called a tomographic inversion. In the past, the tomography technique has been applied in solar physics only for the reconstruction of a scalar field, the electron and ion densities. The principle of scalar field tomography is based on measuring the LOS integral of the absorption or emissivity through the region to be investigated. The observations must be performed from different positions to be able to resolve the 3D structure. The application of scalar field tomography in solar physics has been investigated before by several authors (Davila, 1994; Davila and Thompson, 1992; Zidowitz 1999; Frazin 2000; Frazin & Janzen 2002).

Since we want to reconstruct a vector field, we employ an extension of classical scalar

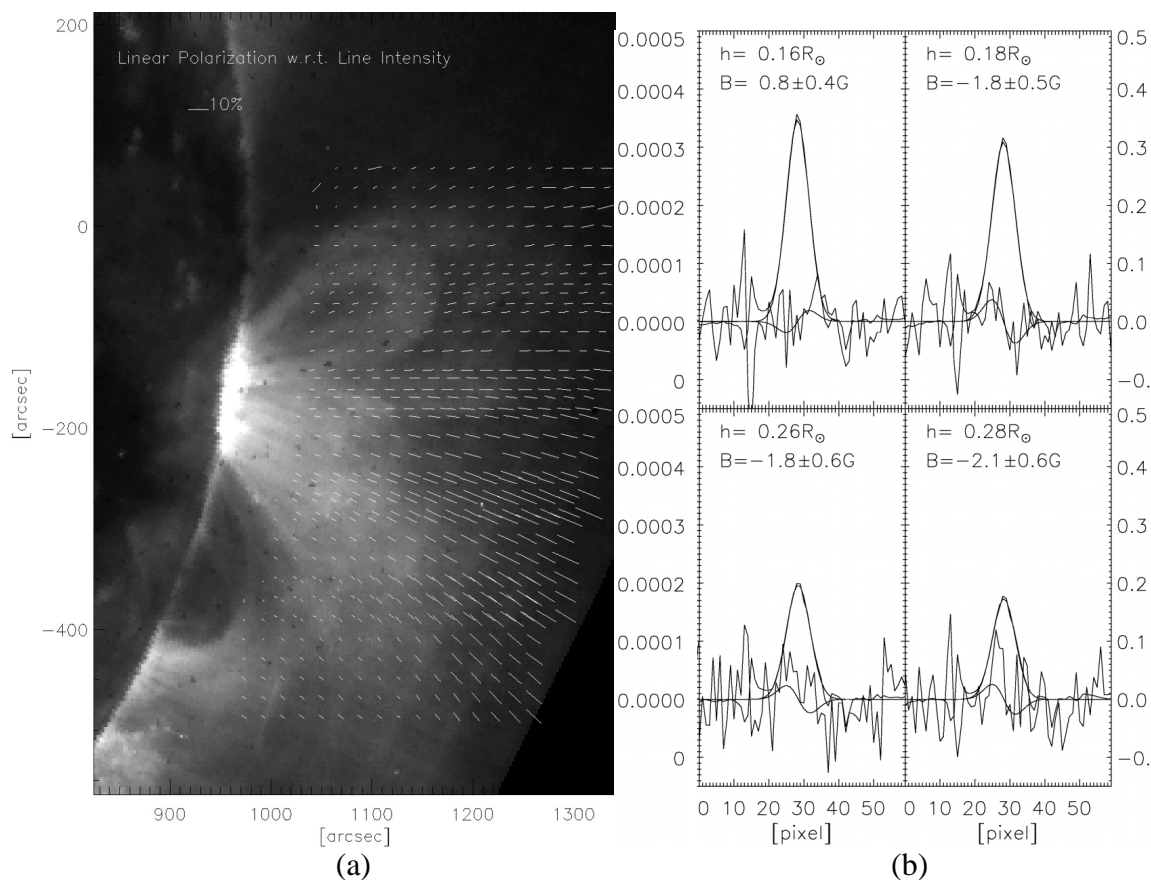

Figure 1.1: An example of the spectropolarimetric observations of the coronal line $\lambda = 10747 \text{ \AA}$ emitted from Fe XIII taken from Lin et al. (2004). The picture on the panel (a) shows the measurements of the Hanle effect as short lines which represent the orientation and, by their length, the degree of the line's linear polarization. The measurements were made above the active region NOAA AR 581 shown in the EUV image (EIT, $\lambda = 284 \text{ \AA}$ of Fe XV) onto which the polarization data is superposed. The graphics on the panel (b) show the fitted Stokes- V profiles due to the longitudinal Zeeman effect (anti-symmetric smooth lines, left-side scale) and fitted Stokes- I profiles (lines having biggest symmetric peak, right-side scale) above the active region. The values of the projection of the magnetic field vector on the LOS which best fits the lines shapes are shown in the inserts. These values were calculated by the standard magnetograph formula without correction for an alignment factor different from unity (see section 5.9).

field tomography, namely vector field tomography (Sparr & Strahlen 1998; Osman & Prince 1997). A variant of vector tomography is used in astrophysical observations, sometimes called Doppler tomography, to derive plasma flow around binary systems and accretion disks (see Boffin et al. (2001) for a review), for the plasma diagnostic in the laboratory plasmas (Howard 1996; Fuchs & Pickalov 1998). To our knowledge, this thesis is the first investigation on whether vector tomography can be used in solar physics for reconstruction of coronal magnetic fields. The tomography of vector fields is fundamentally more difficult than scalar field tomography. While the latter is mildly ill-posed (Natterer 1986), Norton (1989) showed that a whole class of vector fields may be invisible to certain types of observations. Hence, the inversion problem of vector field tomography has to cope with an extended null-space. For example, for the 2D vector field, Norton (1989) showed that the irrotational field component cannot be reconstructed from the LOS projected data.

In the present thesis, we consider the possibility of a reconstruction of the coronal magnetic field by tomographic technique based on possible coronagraph observations of the Hanle and Zeeman effects. A prerequisite for a successful reconstruction is a quantitative description of these effects for the emission lines observed. In this work we focus our considerations where quantitative expressions are needed on two coronal emission lines: $\lambda = 5303 \text{ \AA}$ of Fe xiv, for which many of the Hanle effect observations were made (Arnaud 1982a,b; Querfeld & Smartt 1984;), and $\lambda = 10474 \text{ \AA}$ of Fe xiii for which both the Hanle effect (Arnaud & Newkirk 1987; Habbal et al. 2001) and the longitudinal Zeeman effect observations are in promising progress (Lin et al. 2000, 2004). It is assumed that the observations are made repetitively for one solar rotation. The problems which arise due to the non-stationarity of the coronal magnetic field during the measurement sequence are ignored here.

The 5303 \AA line of Fe xiv (green line) is the brightest forbidden emission line in the visible coronal spectrum. The line was discovered by Young and Harkness during the 1869 total solar eclipse, and identified later by Grotrian (1939) and Edlen (1943). A large progress in intensity observations of the line was reached by the launch of the *SOHO* spacecraft with LASCO coronagraph on board (Brueckner et al. 1995; Schwenn et al. 1997; Inhester et al. 1999). A specially designed coronameter to measure the green line polarization has been built at Pic-du-Midi observatory (Charvin 1971; Arnaud 1982a). For the Hanle effect application it is sufficient to perform line-integrated polarimetric measurements over the line profile. It is not necessary to use spectropolarimetry.

The coronal emission line at 10747 \AA was first observed by B. Lyot (Lyot 1939) in 1936. The first measurements of the polarization of the line were made by Eddy and Malville (1967) during the 1965 eclipse. Later, the Coronal Emission Line Polarimeter (KELP) was constructed by the High Altitude Observatory (HAO) and located at the Sacramento Peak Observatory to provide more precise measurements (Querfeld & Elmore 1976; Querfeld & Smartt 1984). Lin et al. (2000, 2004) have achieved considerable progress in the spectropolarimetric measurements of the line (see Fig. 1.1b) so that they could estimate the longitudinal field strength from the Stokes-V polarization component.

The goal of the thesis is to investigate the possibility to apply vector field tomography based on the polarimetric and spectropolarimetric measurements of the lines mentioned above in order to reconstruct the coronal magnetic field.

The thesis is organized as follows. In the second and third chapters the fundamentals

of scalar and vector field tomography are reviewed. The observational geometry is defined there. Special emphasis is devoted to the question of how an inversion effectively can be improved by regularization (section 2.4), and to the theoretical limitations of vector tomography (section 3.2). A special regularization operator described in section 3.4 will be used in an attempt to overcome these limitations.

The inversion of the LOS integrated data requires a quantitative understanding of how the observed signal is formed. In our case, we need quantitative expressions for the formation of the coronal lines at $\lambda = 5303$ and 10747 \AA . The Zeeman and Hanle effects are qualitatively reviewed in chapter 4. Chapter 5 is devoted to the description of quantitative expressions for the observed polarimetric and spectropolarimetric data in terms of the magnetic field. These expressions are then used in developing an inversion code for the data and in demonstrating its capabilities in chapter 6. The results of our model reconstructions are summarized in the conclusion chapter. In a final outlook we point out the potential of our new method and how further improvements can be made.

2 Scalar Field Tomography

In this chapter the basics of scalar tomography are described. As for many ill-posed problems, the tomography inversion is often stabilized by regularization which is also illustrated in this chapter. Although currently in the inversion program we do not use the traditional form of the regularization presented in this chapter, it can be incorporated into the vector field reconstruction procedure too. Instead we will modify the regularization approach for our purposes as described in chapter 3.

2.1 Formulation of the scalar field tomography problem

For wavelength for which the corona is optically thin, the radiation coming from the corona is a LOS integral of the emissivity in the observed direction. Therefore, it is impossible to reconstruct the spatial distribution of the emissivity from a single (in geometric sense) measurement or projection. The solution space is reduced if we have measurements from many different view points. The reconstruction based on the observations of an object from different view angles is essential for tomography. The possibility of the reconstruction of a function from its projections was firstly studied by Radon (1917). Several decades later, this purely mathematical research formed the basis for the tomography method which was developed for the reconstruction of the X-ray absorption coefficient in human bodies. The first experimental X-ray tomographic scanner was made

Figure 2.1: The 2D slice with the line-of-sight (LOS) in the scalar field tomography.

by Hounsfield (1972), and Cormack (1963,1964) independently discovered some of the algorithms for the reconstruction. The both authors received the Nobel prize for their investigations in 1979. Today, tomography is used in many of the fields: medicine, material structure testing, geophysics, thermonuclear syntheses investigations (TOKAMAK reactors), astrophysics (Doppler tomography for the accretion disks) (Boffin 2001). In solar coronal physics, the use of tomography was first proposed by Wilson (1976) and independently by Davila (1992,1994). Recently, the method was applied for reconstruction of the 3D electron density distribution over the corona from 2.4 to 6.0 R_{\odot} (Frazin 2000; Frazin & Janzen 2002).

Since the distance between the Sun and the Earth orbit is much greater than size of investigated volume of the corona ($\sim 4R_{\odot}$ in diameter in our investigations), it is possible to assume that the rays related to all the pixels of one image are parallel (parallel beam geometry).

Let us make the following two assumptions:

- 1) The corona is stationary during at least one solar rotation, that does not cause to an big error during solar minimum, and rotates together with Sun. So, it is possible to make measurements from the Earth during solar rotation instead of observations from many of spacecrafts.
- 2) The inclination of the Sun's rotation axis with respect to the ecliptic plane (7.26°) is neglected, i.e. we assume that the rotation axis is perpendicular to the line connecting the Sun and the Earth. Then, we can divide the investigated volume into plane-parallel slices in such way, that each of them is perpendicular to the rotation axis, and rays that penetrate one slice do not intersect any other slice; i.e. slices are decoupled, and can be processed independently. This assumption can be avoided twice per year.

So, to reconstruct a 3D configuration of a scalar field $\varepsilon(\mathbf{r})$, it is possible to split the investigated volume in plane-parallel slices with normals along the rotation axis and deal with the 2D problem for every slice separately. Let us consider one slice (Figure 2.1). A single data point defined by the observing angle, ϕ , and distance of the ray from the origin, t , can be described by equation

$$I(\phi, t) = \int_{\text{LOS}_{\phi,t}} \varepsilon(x, y) dl = \int_{\text{LOS}_{\phi,t}} \varepsilon(t \cos \phi - l \sin \phi, t \sin \phi + l \cos \phi) dl. \quad (2.1)$$

The Fourier transform of $I(\phi, t)$ with respect to image position, t , is

$$\begin{aligned} \tilde{I}(\phi, \rho) &= \int I(\phi, t) e^{-i\rho t} dt = \\ &= \int \left[\int_{\text{LOS}_{\phi,t}} \varepsilon(t \cos \phi - l \sin \phi, t \sin \phi + l \cos \phi) e^{-i\rho t} dl \right] dt = \\ &= \int \int \varepsilon(x, y) e^{-i\rho(x \cos \phi + y \sin \phi)} dx dy = \tilde{\varepsilon}(\rho \cos \phi, \rho \sin \phi) = \tilde{\varepsilon}(u, v) \end{aligned} \quad (2.2)$$

Equation (2.2) is the central slice theorem of scalar tomography (Natterer 1986; Kak & Slaney 1987). The right hand side in (2.2) is the two-dimensional Fourier transform of the scalar field function. Therefore, applying the inverse two-dimensional Fourier transform

to \tilde{I} we reconstruct $\varepsilon(x, y)$:

$$\varepsilon(x, y) = \int \int \tilde{\varepsilon}(u, v) e^{i(u x + v y)} du dv = \int \int \tilde{I}(\phi, \rho) e^{i\rho(x \cos \phi + y \sin \phi)} \mathcal{J}(\rho, \phi) d\rho d\phi \quad (2.3)$$

where

$$\mathcal{J}(\rho, \phi) = \begin{vmatrix} \frac{\partial u}{\partial \rho} & \frac{\partial u}{\partial \phi} \\ \frac{\partial v}{\partial \rho} & \frac{\partial v}{\partial \phi} \end{vmatrix} = \begin{vmatrix} \cos \phi & -\rho \sin \phi \\ \sin \phi & \rho \cos \phi \end{vmatrix} = \rho \quad (2.4)$$

is Jacobian determinant of the variable transform $(u, v) \rightarrow (\rho, \phi)$. This way of reconstruction is called the *Fourier method*. Applying this method for every plane, we can reconstruct the scalar function $\varepsilon(\mathbf{r})$ in all three dimensions. The method, however, involves the re-sampling from polar to rectangular coordinates which leads to considerable interpolation. This makes the solution very noisy. In practice, other numerical methods are used. However, the Fourier method is useful for analytical investigations of reconstruction possibilities in principal. Especially, it allows one to proof that a reconstruction from the projections is possible.

The corona extends to the Earth's orbit and further. But we concentrate on measurements only of the part of the corona up to several solar radii. This is called interior problem, and this problem has no unique solution. Only bounded problems have a unique solution (Natterer 1986). Therefore, we need to introduce an outer boundary, so that regions outside of the bounded domain do not make any contribution to the data. This assumption is close to reality because the coronal mass density and strength of magnetic field decrease with distance from the sun very rapidly.

Observations of the solar corona have one more special feature: on some slices, the central part of the image is occulted, i.e. we have data only for $t^2 > R_{\odot}^2 - h^2$ ($h \leq R_{\odot}$), where h is the distance from the ecliptic plane to the reconstructing slice. This is called the exterior problem in tomography, and it is uniquely solvable too (Natterer 1986).

2.2 Matrix formulation of the scalar field tomography problem

Discretizing the LOS integral (2.1) we obtain a set of algebraic equations which can be represented by the matrix equation

$$\mathbf{A} \cdot \mathbf{X} = \mathbf{Y} \quad (2.5)$$

Here, the elements x_j of the column vector \mathbf{X} contain the values of ε in the grid cells with index $j = 1, \dots, n$, and y_i is the data value for the i -th ray, where index $i = 1, \dots, m$ counts both the discrete view angle ϕ and pixel position t . The matrix element a_{ij} represents the LOS projection of volume element j onto LOS related to the pixel i .

Usually, the matrix \mathbf{A} is rectangular ($m \times n$, $m \neq n$) with $\text{rank}(\mathbf{A}) \leq \min(m, n)$. There are two important cases:

- 1) If $\text{rank}(\mathbf{A}) < n$, then the system is underdetermined, and there are infinitely many solutions;
- 2) If $\text{rank}(\mathbf{A}) < m$, then the system is overdetermined, and usually no solutions are possible.

Direct inversion is formally possible if $m = n = \text{rank}(\mathbf{A})$, which is usually not the case. In all other cases it is possible to find some approximation to the real solution (residual), $\tilde{\mathbf{X}}$, by minimizing the distance between $\mathbf{A} \cdot \mathbf{X}$ and \mathbf{Y} (least-square fitting), i.e.

$$\tilde{\mathbf{X}} = \text{argmin}_{\mathbf{X}} |\mathbf{A} \cdot \mathbf{X} - \mathbf{Y}|^2. \quad (2.6)$$

In the underdetermined case, (2.6) yields the solution with the smallest norm, $\min |\tilde{\mathbf{X}}|^2$; in the overdetermined case, we have the solution with the smallest data error, $\min |\mathbf{A} \cdot \tilde{\mathbf{X}} - \mathbf{Y}|^2$.

2.3 Singular Value Decomposition method

One of the methods which is suitable for numerical calculations and allows one to find approximate solutions for both cases listed above is based on the *singular value decomposition* (SVD) of the matrix \mathbf{A} developed by Lanczos (1961).

Any real rectangular matrix (m rows, n columns) can be decomposed into three matrices:

$$\mathbf{A} = \mathbf{U} \cdot \mathbf{\Sigma} \cdot \mathbf{V}^T, \quad (2.7)$$

where \mathbf{U} and \mathbf{V} are $m \times m$ and $n \times n$ matrices, respectively, and both have orthogonal columns so that

$$\mathbf{U}^T \mathbf{U} = \mathbf{1}_m, \mathbf{V}^T \mathbf{V} = \mathbf{1}_n. \quad (2.8)$$

The columns of the matrices \mathbf{U} and \mathbf{V} are the left and right singular eigenvectors of \mathbf{A} , respectively. $\mathbf{\Sigma}$ is a square $n \times n$ matrix with off-diagonal elements set to be zero and non-negative diagonal elements, σ_i (with $i = 1, \dots, n$), which are the eigenvalues (singular values) of the matrix \mathbf{A} usually ordered with descending magnitude. In the case of $\text{rank}(\mathbf{A}) < n$, all the rest $n - \text{rank}(\mathbf{A})$ diagonal elements in $\mathbf{\Sigma}$ are set to zero.

The residual of (2.5) is calculated by pseudoinverse of \mathbf{A} :

$$\tilde{\mathbf{X}} = (\mathbf{V} \mathbf{\Sigma}^{-1} \mathbf{U}^T) \mathbf{Y}, \quad (2.9)$$

where the elements λ_i of the inverse matrix $\mathbf{\Sigma}^{-1}$ are equal to $1/\sigma_i$. The singular values σ_i strongly decrease with i . Therefore, to avoid a big error in λ_i for the large i , the values of λ_i corresponding to the small singular values are set to zero, because small σ_i means that the measurements were insensitive to the structure represented by eigenvector \mathbf{u}_i (i -th column of the \mathbf{U}).

For problems which involve integral equations, the left and right singular vectors \mathbf{u}_i and \mathbf{v}_i tend to an oscillatory behaviour with increasing index i , i.e., with decreasing value of σ_i . Therefore, setting these elements to zero (cut-off), the high-frequency components in the solution are damped, i.e., the solution is smoother.

The SVD method is only possible for moderately small ($\text{rank}(\mathbf{A}) \lesssim 10^3$) matrices. For the high-rank matrices, it is more suitable to use algorithms based on the algebraic iterative techniques.

2.4 Regularization

In astrophysics we usually have underdetermined problems. Moreover, data obtained from measurement process are always contaminated by noise. So $\mathbf{Y} = \mathbf{Y}_0 + \mathbf{E}$, where

\mathbf{Y}_0 is the unperturbed data, and \mathbf{E} is a vector containing random noise. Therefore, to stabilize the problem, it is necessary to add more information about the possible solution. One type of additional information can be the property that the residual norm $|\tilde{\mathbf{X}}|$ must be as small as possible. To find a solution in this case, we should minimize $|\mathbf{A} \cdot \mathbf{X} - \mathbf{Y}|^2$ and $|\mathbf{X}|^2$ together, which is the simplest form of the regularization method. The regularization method was developed independently by Phillips (1962) and, in a more general way, by Tikhonov (1963). For the problem (2.5) the regularized solution can be found by the minimization:

$$\tilde{\mathbf{X}}_\mu = \operatorname{argmin}_{\mathbf{X}} (|\mathbf{A} \cdot \mathbf{X} - \mathbf{Y}|^2 + \mu |\mathbf{R} \cdot \mathbf{X}|^2), \quad (2.10)$$

where the second term is a general linear regularization term with the regularization matrix \mathbf{R} and regularization parameter μ . If \mathbf{R} is a unit matrix, then we have a zero-order regularization term. If $\mathbf{R} \cdot \mathbf{X}$ represents a finite difference approximation to the first derivative, there is first-order regularization; and, analogously, when $\mathbf{R} \cdot \mathbf{X}$ represents a finite difference approximation to the second derivative, we have a second-order regularization, and so on for the higher orders. The general solution of the minimizing problem (2.10) is

$$\tilde{\mathbf{X}}_\mu = \left[(\mathbf{A}^T \mathbf{A} + \mu^2 \mathbf{R}^T \mathbf{R})^{-1} \mathbf{A}^T \right] \mathbf{Y}. \quad (2.11)$$

The eigenvalues of matrix $\mathbf{A}^T \mathbf{A}$ are σ_i^2 . Even if they are small or zero for large i , the eigenvalues of $(\mathbf{A}^T \mathbf{A} + \mu^2 \mathbf{R}^T \mathbf{R})$ are finite, and the smallest is controlled by μ .

The solution (2.11) depends on the chosen regularization parameter μ . What is the optimal value of μ ? To answer this question, it is very convenient to use the L-curve method (Miller 1970; Lawson & Hanson 1974; Hansen 1993). The L-curve is a log-log plot of the residual norm $|\mathbf{A} \cdot \tilde{\mathbf{X}}_\mu - \mathbf{Y}|^2$ versus the norm $|\mathbf{R} \cdot \tilde{\mathbf{X}}_\mu|^2$ of the regularization term. The curve is often has an "L" shape (Fig. 2.2).

The error $\tilde{\mathbf{X}}_\mu - \mathbf{X}_0$ of the regularized solution consists of two components: the perturbation error from the error \mathbf{E} in the data and regularization error due to the regularization of the error-free data component \mathbf{Y}_0 .

The almost vertical part of the L-curve corresponds to the solutions where the regularization error dominates, i.e. where the solution is very smooth due to the big value

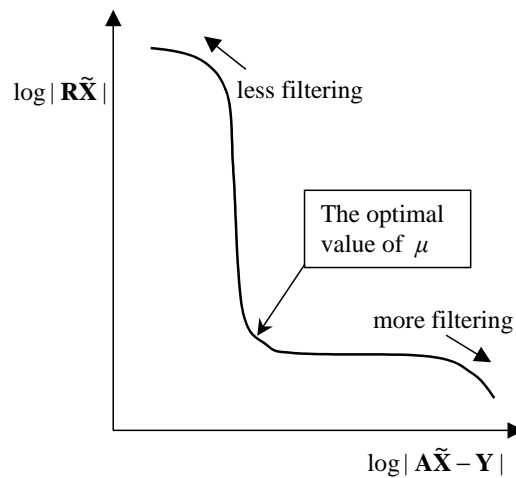

Figure 2.2: The L-curve

of μ , and therefore the regularization term $|\mathbf{R} \cdot \tilde{\mathbf{X}}_\mu|^2$ changes a little with the regularization parameter. The almost horizontal part of the curve corresponds to solutions that are dominated by the data error, and therefore the smoothness of the solution rapidly decreases. The logarithmic scale emphasizes this difference of the vertical and horizontal parts (Hansen 1992; Hansen & O'Leary 1993). Therefore, it is logical to choose the optimum value of μ which corresponds to the point closest situated to the corner of the L-curve (Hansen & O'Leary 1993). It is impossible to find a solution that corresponds to a point below the L-curve. Any regularized solution must be on or above (when it was not enough number of iterations proceeded) this curve.

3 Vector Tomography

The basic introduction to the vector tomography is presented here. The possibility of the reconstruction of the irrotational and solenoidal components of the 3D vector field are considered from a theoretical point of view. Then, for practical implementation the discrete formulation of the vector tomography problem in a matrix form is introduced. A modified regularization procedure for the vector tomography of the magnetic field is described.

3.1 The formulation of the vector field tomography problem

Vector tomography data for optically thin objects is generally expressed by line-of-sight integrals like for scalar field tomography, but instead of a scalar function $\varepsilon(\mathbf{r})$ we must reconstruct a vector argument $\mathbf{B}(\mathbf{r})$ of a scalar function S . The observations can be expressed as

$$I(\phi, \theta, x_p, y_p) = \int_{\text{LOS}(\phi, \theta, x_p, y_p)} S(\mathbf{r}, \mathbf{B}(\mathbf{r}), \hat{\mathbf{e}}_{\phi, \theta}) dl, \quad (3.1)$$

where angles ϕ and θ define the direction $\hat{\mathbf{e}}_{\phi, \theta}$ of the LOS in a spherical coordinate system, x_p and y_p are coordinates of the image pixel in the projection plane (Fig. 3.1). Contrary to scalar field tomography, not only the integration domain but also the integrand, function S in (3.1), depends on the LOS direction.

Depending on the physical effect used in the measurements, the function S can depend on some components of \mathbf{B} . For example, the longitudinal component, $B_{\parallel} = \mathbf{B} \cdot \hat{\mathbf{e}}_{\phi, \theta}$ for the Faraday- and Zeeman-effect, or the direction of the transverse component $\mathbf{B}_{\perp} = \mathbf{B} \times \hat{\mathbf{e}}_{\phi, \theta}$ for the Hanle-effect with respect to the LOS:

$$\begin{pmatrix} I^{\parallel} \\ I^{\perp} \end{pmatrix}_{\phi, \theta, x_p, y_p} = \int_{\text{LOS}(\phi, \theta, x_p, y_p)} \begin{pmatrix} S^{\parallel}(\mathbf{r}, \mathbf{B} \cdot \hat{\mathbf{e}}_{\phi, \theta}) \\ S^{\perp}(\mathbf{r}, \mathbf{B} \times \hat{\mathbf{e}}_{\phi, \theta}) \end{pmatrix} dl. \quad (3.2)$$

The special expressions for S^{\parallel} and S^{\perp} (Zeeman and Hanle observations) will be derived later in the chapter 5. Here we will consider simplified, linearized expression $S^{\parallel} = f(\mathbf{r}) (\mathbf{B} \cdot \hat{\mathbf{e}}_{\phi, \theta}) \equiv \mathbf{V}(\mathbf{r})$ to derive some theoretical results. Firstly, the linearization is a good approximation for the actual kernel for Faraday- and Zeeman-effect observations. Secondly, the limitations of a reconstruction with the linearized kernel will almost certainly prevail for the non-linear problem.

3.2 Vector tomography for the LOS projection data

The first row of (3.2) connected with B_{\parallel} is known as vectorial ray transform. The tomography problem for the vectorial ray transform is investigated for the case of velocity field of a fluid flow (Sparr & Strahlen 1998; Osman & Prince 1997; and references therein). In this case the data for the coronal observations of the longitudinal Zeeman or Faraday effects is expressed by

$$\begin{aligned} I^{\parallel}(\phi, \theta, x_p, y_p) &= \int_{\text{LOS}(\phi, \theta, x_p, y_p)} f(\mathbf{r}) \mathbf{B}_{\parallel}(\mathbf{r}) d\ell = \int_{\text{LOS}(\phi, \theta, x_p, y_p)} \mathbf{V}_{\parallel}(\mathbf{r}) d\ell = \\ &= \int_{\text{LOS}(\phi, \theta, x_p, y_p)} (V_x \cos \phi \sin \theta + V_y \sin \phi \sin \theta + V_z \cos \theta) d\ell, \end{aligned} \quad (3.3)$$

where $f(\mathbf{r})$ is some scalar function of position in space (in the case of the Faraday effect, this function is the electron density), and $\mathbf{V} = f\mathbf{B}$. In the case when the observer positions are confined to the equatorial plane $\theta = \pi/2$, we can decompose the reconstruction

Figure 3.1: The 3D view of the tomography geometry

domain into plane-parallel slices normal to the z -axis. Then, from eq. (3.3) one can see that for the plane-parallel case only two components of the vector field, V_x and V_y , contribute to the data. Therefore, having I^{\parallel} -type data from plane-parallel measurements, it is impossible to fully reconstruct a vector field without additional constraint. This, however, is the situation for most observing space crafts usually located in the plane of the ecliptic.

But even the reconstruction of the V_x and V_y components which could be performed independently for each plane is not unique. Norton (1989) showed that the irrotational part of a 2D vector field cannot be reconstructed from the vectorial ray transform. It can be reconstructed uniquely if $\nabla \cdot \mathbf{V} = 0$ by solving a boundary value problem.

We extend the work of Norton (1989) to the case of a 3D vector field $\mathbf{V}(\mathbf{r})$ for which we have a Helmholtz decomposition:

$$\mathbf{V} = \nabla \times \Psi + \nabla \cdot \Phi \quad (3.4)$$

where Ψ and Φ are the vector and scalar potentials respectively, $\nabla \times \Psi$ and $\nabla \cdot \Phi$ are the solenoidal and irrotational parts of \mathbf{V} , respectively. The vectorial ray transform (3.3) can be rewritten in the form

$$\begin{aligned} I_{\phi,\theta}(x_p, y_p) = & \cos \phi \sin \theta \iiint_{\text{Corona}} V_x(x, y, z) \delta_{x_p} \delta_{y_p} dx dy dz + \\ & + \sin \phi \sin \theta \iiint_{\text{Corona}} V_y(x, y, z) \delta_{x_p} \delta_{y_p} dx dy dz + \\ & + \cos \theta \iiint_{\text{Corona}} V_z(x, y, z) \delta_{x_p} \delta_{y_p} dx dy dz, \end{aligned} \quad (3.5)$$

where the line integration is written as a volume integral with suitable Dirac-delta functions

$$\begin{aligned} \delta_{x_p} &= \delta(x \sin \phi - y \cos \phi - x_p), \\ \delta_{y_p} &= \delta(-x \cos \phi \cos \theta - y \sin \phi \cos \theta + z \sin \theta - y_p), \end{aligned} \quad (3.6)$$

are the Dirac delta-functions. Substituting (3.5) into the 2D Fourier transform of $I_{\phi,\theta}(x_p, y_p)$ with respect to the image position (x_p, y_p) ,

$$\tilde{I}_{\phi,\theta}(k_1, k_2) = \iint_{\text{Image of } (\phi,\theta)} I_{(\phi,\theta)}(x_p, y_p) e^{-i(k_1 x_p + k_2 y_p)} dx_p dy_p, \quad (3.7)$$

and changing the order of integration, one obtains

$$\tilde{I}_{\phi,\theta}(k_1, k_2) = \cos \phi \sin \theta \tilde{V}_x(u, v, w) + \sin \phi \sin \theta \tilde{V}_y(u, v, w) + \cos \theta \tilde{V}_z(u, v, w), \quad (3.8)$$

where \tilde{V}_x , \tilde{V}_y and \tilde{V}_z are the 3D-Fourier transforms of V_x , V_y and V_z respectively, with respect to the position in the corona (x, y, z) , and

$$u = k_1 \sin \phi - k_2 \cos \phi \cos \theta, \quad v = -k_1 \cos \phi - k_2 \sin \phi \cos \theta, \quad w = k_2 \sin \theta. \quad (3.9)$$

If we have plane-parallel slices ($\cos \theta = 0$), then equation (3.8) represents the central-slice theorem for a 2D vector field. Taking into account (3.4) and (3.9), the 3D Fourier

transform of the components of the vector \mathbf{V} are

$$\begin{aligned}\tilde{V}_x(u, v, w) &= iv\tilde{\Psi}_z(u, v, w) - iw\tilde{\Psi}_y(u, v, w) + iu\tilde{\Phi}(u, v, w), \\ \tilde{V}_y(u, v, w) &= iw\tilde{\Psi}_x(u, v, w) - iu\tilde{\Psi}_z(u, v, w) + iv\tilde{\Phi}(u, v, w), \\ \tilde{V}_z(u, v, w) &= iu\tilde{\Psi}_y(u, v, w) - iv\tilde{\Psi}_x(u, v, w) + iw\tilde{\Phi}(u, v, w).\end{aligned}\quad (3.10)$$

Placing (3.10) into (3.8), one has

$$\begin{aligned}\tilde{I}_{\phi, \theta}(k_1, k_2) &= i(k_1 \cos \phi \cos \theta + k_2 \sin \phi) \tilde{\Psi}_x + \\ &+ i(k_1 \sin \phi \cos \theta - k_2 \cos \phi) \tilde{\Psi}_y - ik_1 \sin \theta \tilde{\Psi}_z,\end{aligned}\quad (3.11)$$

which is independent on the source $\tilde{\Phi}$ of the vector field. This means that even with measurements from all possible directions in 3D space, it is impossible to reconstruct the irrotational component of the vector field.

3.3 Matrix formulation of the vector tomography problem

Like in the scalar field tomographic problem, vector tomography for the I^{\parallel} -type data (3.2) can be represented in matrix equation form as well:

$$\mathbf{A} \cdot \mathbf{X} = \mathbf{Y}.\quad (3.12)$$

Here, the components x_{3j-k} ($k = 2, 1, 0$) of the column-vector \mathbf{X} contain components of the vector \mathbf{B} in the j -cell, and y_i is the data value for the i -th ray, where the index $i = 1, \dots, m$ counts both view angles, ϕ and θ , and pixel position (x_p, y_p) . The matrix elements $a_{i,3j-k}$ represents the projection of volume element j onto the LOS, related to the pixel i , multiplied with the components of a unit vector co-directed with the LOS; i.e. $a_{i,3j-k}$ are the components of vector $\Delta \mathbf{l}$. Here we do not take into the account the electron density dependence of the measured data. The way how to include this dependence into the matrix \mathbf{A} will be described in section 6.3.

3.4 Special regularization for coronal vector tomography

Taking into account that magnetic field is free of divergence ($\nabla \cdot \mathbf{B} = 0$), it is possible to introduce a regularization term into the minimizing function of the form:

$$F = F_{\text{tomo}} + \mu F_{\text{reg}} = \sum_{\text{all LOS}} (I^{\text{sim}} - I^{\text{obs}})^2 + \mu \sum_{\text{Corona}} |\nabla \cdot \mathbf{B}(\mathbf{r})|^2.\quad (3.13)$$

By applying finite difference approach to $\nabla \cdot \mathbf{B}$, one gets a matrix form for the regularization term:

$$F_{\text{reg}} = |\mathbf{A}_{\text{reg}} \cdot \mathbf{X} - \mathbf{Y}_b|^2,\quad (3.14)$$

where the column vector \mathbf{X} is the same as in (3.12). The number of rows in \mathbf{A}_{reg} is equal to the number of cells involved in the calculations (equal to the number of elements in \mathbf{X}

divided by three). Matrix \mathbf{Y}_b contains boundary values defined from the measurements of the magnetic field at the photospheric level.

This regularization is different from the one presented for the scalar field tomography, where the regularization term represents the roughness of the solution and its minimization ensures a certain degree of smoothness of the solution. The regularization $\nabla \cdot \mathbf{B} = 0$ has large null space and acts only on the irrotational part of the field. The null space is therefore composed of all divergencefree fields compatible with the measured boundary condition \mathbf{Y}_b . It is well known (Bellan 2000) that the field with the smallest energy, i.e. $|\mathbf{X}|^2 = \sum_{\text{corona}} |\mathbf{B}|^2$, within this null space is the potential field that fits the boundary conditions. Many solution algorithms for (3.13) implicitly minimize the solution norm $|\mathbf{X}|^2$. Hence, such an algorithm will yield the potential field model of the corona if no tomography data is present and only the second term in (3.13) is minimized. Any tomography data will yield possible non-potential extensions of the coronal magnetic field. The numerical implementation of the term will be further described in the section 6.2.

4 The possible effects used for deriving the magnetic field

4.1 Zeeman-effect

The Zeeman-effect was discovered by Zeeman (1897), and consists in the splitting of individual spectral lines of an emission spectrum into three or more polarized components in presence of a magnetic field. When spectral lines split into the three components, σ_b , σ_r and π , the effect is known as normal Zeeman effect. The case when spectral lines split into more than three components is known as anomalous Zeeman effect (Figure 4.1).

In the presence of a magnetic field each level with the magnetic quantum number M_J gets additional energy

$$E_B = gM_J\hbar\frac{eB}{2m_e} = g\hbar\omega_L, \quad (4.1)$$

where e is the elementary charge, B the magnetic field strength, m_e the mass of the electron, \hbar the Planck constant, ω_L is the Larmour frequency, and g is the Lande factor depending on the quantum numbers L , S , J and M_J : L is for orbital angular momentum of the electrons, S is their spin quantum number, J is the associated total angular momentum quantum number, and M_J is the quantum number for the component of total angular momentum along the direction of the magnetic field (magnetic quantum number). The Landé factor is

$$g = \frac{3}{2} + \frac{S(S+1) - L(L+1)}{2J(J+1)}. \quad (4.2)$$

Each level with total angular momentum J splits into $(2J+1)$ sublevels. As a result, the frequencies related to the transitions between the lower level with J_l and upper level with J_u are defined by

$$\nu_{J_l M_l \leftrightarrow J_u M_u} = \nu_0 + \frac{eB}{2m_e} \cdot (g_u M_u - g_l M_l) \quad (4.3)$$

where ν_0 is the frequency of the line in the absence of magnetic field, g_u and g_l are the Landé factors for the upper and lower levels respectively, and M_u and M_l are the magnetic quantum numbers for these levels.

The selection rules for allowed electric dipole (E1) transitions are:

$$\begin{aligned} \Delta J &= 0, \pm 1, \quad J_u = 0 \rightarrow J_l = 0 \text{ is forbidden,} \\ \Delta L &= 0, \pm 1, \quad \Delta S = 0, \\ \Delta M &= 0, \pm 1. \end{aligned} \quad (4.4)$$

Figure 4.1: Zeeman transitions.

The selection rule for magnetic dipole (M1) transitions is $\Delta M = 0, \pm 1$. The lines 5303 Å and 10747 Å of the Fe XIV and Fe XIII ions, respectively, are forbidden for the electric dipole (E1) transitions but allowed for the magnetic dipole (M1) transitions. The π -components correspond to the transitions with $\Delta M = 0$, and σ -components – with $\Delta M = \pm 1$ (Fig. 4.1). If the LOS is parallel to the direction of the magnetic field, clockwise polarization at frequency ν_{σ_b} will be observed and counterclockwise at the frequency ν_{σ_r} (longitudinal Zeeman-effect), where

$$\begin{aligned} \nu_{\sigma_b} &= \nu_0 - \Delta\nu_Z, \\ \nu_{\sigma_r} &= \nu_0 + \Delta\nu_Z, \end{aligned} \quad (4.5)$$

$$\Delta\nu_Z = \frac{eB}{2m_e} \cdot |g_u M_u - g_l M_l|.$$

If we observe along the direction perpendicular to the magnetic field vector, we see a linear polarization parallel to the vector \mathbf{B} at frequency $\nu = \nu_0$ and a linear polarization perpendicular to the \mathbf{B} at $\nu = \nu_0 \pm \Delta\nu_Z$ (transversal Zeeman-effect). The intensity of the circularly polarized signal corresponding to the longitudinal Zeeman-effect is much higher than intensity of the linear polarized signal for the transversal one.

4.2 Hanle-effect

The Hanle-effect was discovered by Hanle in 1923 (Hanle 1924). Here we briefly describe the key points of this effect. A more detailed description can be found in Mitchel & Zemansky (1934), and Landi & Landolfi (2004). Let us consider scattering of unpolarized light of an atom with $J_l = 0$ and $J_u = 1$ without magnetic field (Fig. 4.2a). If no magnetic field present, the atom can be described by three independent linear oscillators. The radiation scattered along the direction of incident light is unpolarized. But if we observe from a direction perpendicular to the incident light, we find linear polarization.

Let us introduce now a magnetic field parallel to the x -axis (Fig. 4.2b,c). Then the atom must be described by a linear oscillator parallel to the magnetic field and two counter-rotating circular oscillators in the yz -plane oscillating at frequencies $\omega_0 - \omega_L$ and

Figure 4.2: Polarization of forward and perpendicular scattered radiation in the absence of magnetic field (a) and in the presence of the field parallel to the perpendicular LOS direction (b,c).

$\omega_0 + \omega_L$, where ω_L is the Larmor frequency. The resulting trajectory of the electron in the yz -plane is (Trujillo Bueno 2000)

$$\begin{cases} y(t) = A \cdot e^{-t/2\tau} \cos(\omega_L t) \cos(\omega_0 t), \\ z(t) = A \cdot e^{-t/2\tau} \sin(\omega_L t) \cos(\omega_0 t), \end{cases} \quad (4.6)$$

where τ is a life time.

When the magnetic field is strong ($\omega_L \tau \gg 1$), the oscillation axis rotates several times (Fig. 4.2c). The trajectory of the electron in yz -plane is a "daffodil", and the scattered light into the perpendicular direction is totally unpolarized. For the forward scattering case we have a maximum amount of linear polarization.

In case of the weak magnetic field ($\omega_L \tau \approx 1$), the oscillation axis rotates only for some angle α (figure 4.2b). The electron now describes a "rosette" in the yz -plane, with result that the radiation scattered into the x -direction will be partially polarized. In comparison with non-magnetic case, we have a decreased degree of polarization and rotation of the polarization plane.

4.3 Faraday-effect

Linearly polarized radiation can be described as the superposition of two circularly polarized components with opposite rotation. The total electric field vector in case of a propagation along the z -direction is splitted in a sum of two electric vectors, \mathbf{E}_R and \mathbf{E}_L , corresponding to the right- and left-hand circularly polarized field components,

$$\mathbf{E} = \mathbf{E}_R + \mathbf{E}_L = (\hat{\mathbf{e}}_x + i\hat{\mathbf{e}}_y)E_{0R}e^{i(k_R z - \omega t)} + (\hat{\mathbf{e}}_x - i\hat{\mathbf{e}}_y)E_{0L}e^{i(k_L z - \omega t)}, \quad (4.7)$$

where E_{0L} and E_{0R} are the amplitudes for the left- and right-hand circularly polarized components, respectively, k_L and k_R are their respective wave vectors in the z -direction, ω is the cyclic frequency, and t is the time, $\hat{\mathbf{e}}_x$ and $\hat{\mathbf{e}}_y$ are the unit vectors defining the x - and y -directions, respectively.

The polarization angle ϕ is defined through the ratio of the x - and y -components of the electric field vector,

$$\cot \phi = \frac{E_x}{E_y} = \frac{\frac{E_{0L}}{E_{0R}} \cos(k_L z + \omega t) + \cos(k_R z - \omega t)}{\frac{E_{0L}}{E_{0R}} \sin(k_L z + \omega t) + \sin(k_R z - \omega t)}, \quad (4.8)$$

and for the circular polarization, when $E_{0R} = E_{0L}$, we have

$$\cot \phi = \cot \left(\frac{k_L - k_R}{2} z \right). \quad (4.9)$$

The values of the propagation vectors k_L and k_R may differ in a magnetized plasma. We consider radio or light waves for which the frequency ω is much larger than plasma frequency

$$\omega_p = \frac{n_e e^2}{m_e \epsilon_0}, \quad (4.10)$$

where n_e is the electron density, m_e the electron mass, e the elementary charge and ϵ the electric constant. For our purpose the wave numbers as derived in magneto-ionic theory (Stix 1962) therefore are

$$k_L = \frac{\omega}{c} \sqrt{1 - \frac{\omega_p^2}{\omega(\omega + \omega_e)}}, \quad k_R = \frac{\omega}{c} \sqrt{1 - \frac{\omega_p^2}{\omega(\omega - \omega_e)}}. \quad (4.11)$$

Here, c is the speed of light,

$$\omega_e = \frac{eB_z}{m_e} \quad (4.12)$$

is the electron gyrofrequency, and B_z is the projection of the magnetic field vector on the propagation direction z . For the radio waves and typical coronal magnetic field strength $\omega \gg \omega_e$. So, the total rotation of the polarization plane of the linearly polarized electromagnetic wave after passing the corona is

$$\phi = \frac{e^3}{2\pi m_e^2 c^2 (\omega/2\pi)^2} \int n_e B_z dz. \quad (4.13)$$

Since the rotation angle is inversely proportional to the square of radiation frequency, the Faraday-effect is more effective for radio waves. The Faraday rotation can be used for the determination of the magnetic field in the corona by polarization measurements before and during the occultation by the Sun of a distant linearly polarized radio source. For example, Stelzried et al. (1970) observed this effect between $4 - 12R_\odot$ during the Pioneer 6 passage behind the Sun. Golnev et al. (1969) found a magnetic field strength of 10^{-2} G for the corona at a distance of $5R_\odot$ during the occultation of the Crab Nebula.

5 The line formation of magnetically sensitive lines

The processes of the formation of polarized emission of coronal lines in presence of a magnetic field is briefly described in this chapter. The emission lines are formed due to atomic transitions from an upper excited state to lower one. The excited state of an atom in the corona is mainly caused by thermal collisions or by radiation incident from the photosphere. The polarization of the emitted radiation is due to the anisotropy of the incident pumping radiation and the anisotropy induced by the magnetic field. The magnetograph formula expresses the dependence of the Stokes- I and $-V$ spectra from the LOS projection of the magnetic field vector. This formula is the background for the tomographic reconstruction based on the longitudinal Zeeman-effect data. The expressions for calculation of the Stokes- I , $-Q$ and $-U$ vectors, integrated over the line profiles for the infrared (10747 Å) and green (5303 Å) lines, are presented in the sections 5.10 and 5.11. These expressions are directly involved in the reconstruction procedure using the Hanle-effect data described in the next chapter.

5.1 Stokes vector

The electric field vector of the monochromatic electromagnetic wave propagating in the z -direction is expressed by

$$E_x(t) = E_x \cos(\omega t - \phi_x) \quad (5.1)$$

$$E_y(t) = E_y \cos(\omega t - \phi_y) \quad (5.2)$$

where E_x and E_y are the amplitudes, ϕ_x and ϕ_y are phase shifts, ω is the cyclic frequency and t the time. Instead of these four parameters describing the wave (E_x, E_y, ϕ_x, ϕ_y), G.Stokes introduced another set:

$$I_\omega = E_x^2 + E_y^2, \quad (5.3)$$

$$Q_\omega = E_x^2 - E_y^2, \quad (5.4)$$

$$U_\omega = 2E_x E_y \cos(\phi_x - \phi_y), \quad (5.5)$$

$$V_\omega = 2E_x E_y \sin(\phi_x - \phi_y). \quad (5.6)$$

These Stokes parameters satisfy the relationship:

$$I_\omega^2 = Q_\omega^2 + U_\omega^2 + V_\omega^2. \quad (5.7)$$

The Stokes parameters are chosen in the way that I_ω describes the total intensity of polarized monochromatic light, Q_ω is the intensity of linearly polarized radiation along x -axis minus intensity of linearly polarized radiation along y -axis, U_ω the intensity of linearly polarized radiation along the unit vector $(\hat{e}_x + \hat{e}_y)/\sqrt{2}$ minus intensity of linearly polarized radiation along $(-\hat{e}_x + \hat{e}_y)/\sqrt{2}$, and V_ω the intensity of right circularly polarized radiation minus the intensity of left circularly polarized radiation.

But the monochromatic approximation of the wave is far from reality. A more realistic description of electromagnetic radiation is the superposition of many wave packets having a limited extension in space and time (quasi-monochromatic radiation). Therefore the Stokes-parameters now is expressed by averaging over the statistical distribution of the wave packets:

$$I = \langle E_x^2 + E_y^2 \rangle, \quad (5.8)$$

$$Q = \langle E_x^2 - E_y^2 \rangle, \quad (5.9)$$

$$U = \langle 2E_x E_y \cos(\phi_x - \phi_y) \rangle, \quad (5.10)$$

$$V = \langle 2E_x E_y \sin(\phi_x - \phi_y) \rangle. \quad (5.11)$$

Now $I^2 \geq Q^2 + U^2 + V^2$, and total intensity, I , is a sum of the intensities of the polarized component and unpolarized one:

$$I = \sqrt{Q^2 + U^2 + V^2} + I_{\text{unpolarized}}. \quad (5.12)$$

The relation

$$p = \frac{\sqrt{Q^2 + U^2 + V^2}}{I} \quad (5.13)$$

defines the degree of polarization.

5.2 Radiative Transfer for the Polarized Radiation

Under the assumption that the corona is optically thin, the radiative transfer equation (RTE) for polarized radiation takes form

$$\frac{d\mathbf{S}}{dl} = \mathbf{J}, \quad (5.14)$$

where $\mathbf{S} = (I, Q, U, V)^T$ is the Stokes vector (sign "T" here notes matrix transpose operation), $\mathbf{J} = (\varepsilon_I, \varepsilon_Q, \varepsilon_U, \varepsilon_V)^T$ is the emission vector, and l is the coordinate along the LOS. The emission coefficients in the emission vector for the magnetic dipole transition for polarized radiation can be written in a similar way like for the unpolarized case, but we have to take into the account the dependence of the Stokes components on the orientation of the magnetic dipole with respect to the chosen reference system (Fig. 5.1) (Landi & Landolfi 2004):

$$\begin{aligned} \varepsilon_I &= \text{Re}(f_{++} + f_{--}), \\ \varepsilon_Q &= -\text{Re}(f_{+-} + f_{-+}), \\ \varepsilon_U &= \text{Im}(f_{+-} - f_{-+}), \\ \varepsilon_V &= \text{Re}(f_{++} - f_{--}), \end{aligned} \quad (5.15)$$

where for the case of magnetic dipole transitions

$$f_{\alpha\beta} = \frac{2h\nu^3}{c^2} \frac{4\pi^3\nu}{ch} N \times \sum_{mm'n} [\boldsymbol{\mu}_{mn} \cdot \boldsymbol{\Omega} \times \hat{\mathbf{e}}_\alpha(\boldsymbol{\Omega})] [\boldsymbol{\mu}_{nm'} \cdot \boldsymbol{\Omega} \times \hat{\mathbf{e}}_\beta(\boldsymbol{\Omega})^*] \rho_{m'm} \Phi(\nu_{mn} - \nu). \quad (5.16)$$

Here, $\boldsymbol{\mu}_{mn}$ is magnetic dipole moment for the transition $m \rightarrow n$, $\rho_{m'm}$ is a density matrix element that should be found by solving statistical-equilibrium equations, and N is the density of the radiating ions. Here the reference system defined by the unit vectors $(\hat{\mathbf{e}}_a, \hat{\mathbf{e}}_b)$ was replaced by the circulating reference system defining by the unit vectors

$$\begin{aligned} \hat{\mathbf{e}}_{-1}(\boldsymbol{\Omega}) &= \frac{1}{\sqrt{2}} [\hat{\mathbf{e}}_a(\boldsymbol{\Omega}) + i\hat{\mathbf{e}}_b(\boldsymbol{\Omega})], \\ \hat{\mathbf{e}}_{+1}(\boldsymbol{\Omega}) &= \frac{1}{\sqrt{2}} [-\hat{\mathbf{e}}_a(\boldsymbol{\Omega}) + i\hat{\mathbf{e}}_b(\boldsymbol{\Omega})]. \end{aligned} \quad (5.17)$$

The function Φ is a generalized complex line profile expressed in units of Doppler width,

$$\Delta\lambda_D = \lambda_0 \frac{v_T}{c}, \quad \Delta\nu_D = \nu_0 \frac{v_T}{c}, \quad (5.18)$$

where v_T is the thermal velocity, c the speed of light, and λ_0 and ν_0 define the position of the gravity center of the spectrum in wavelength or frequency (when a macroscopic velocity is not taken into account). The profile of the function Φ can be written as:

$$\Phi = \frac{1}{\sqrt{\pi}\Delta\nu_D} \cdot H\left(\frac{\nu_{mn} - \nu}{\Delta\nu_D} - v_A, a\right) + \frac{i}{\sqrt{\pi}\Delta\nu_D} \cdot L\left(\frac{\nu_{mn} - \nu}{\Delta\nu_D} - v_A, a\right), \quad (5.19)$$

where

$$a = \frac{\Gamma}{\Delta\nu_D} = \frac{\Gamma\lambda_0^2}{c\Delta\lambda_D}. \quad (5.20)$$

Figure 5.1: The unit vector of reference direction, $\hat{\mathbf{e}}_a$, and associated unit vector $\hat{\mathbf{e}}_b$ so that $\hat{\mathbf{e}}_a \times \hat{\mathbf{e}}_b \parallel \boldsymbol{\Omega}$, where $\boldsymbol{\Omega}$ is propagation direction (LOS direction).

Here $\Gamma = (\gamma_m + \gamma_n)/4\pi$ is the damping parameter, and γ_m and γ_n are probabilities per unit time that the atom leaves the level m or n .

The functions

$$H(v, a) = \frac{a}{\pi} \int_{-\infty}^{+\infty} e^{-y^2} \frac{1}{(v-y)^2 + a^2} dy, \quad (5.21)$$

$$L(v, a) = \frac{1}{\pi} \int_{-\infty}^{+\infty} e^{-y^2} \frac{v-y}{(v-y)^2 + a^2} dy \quad (5.22)$$

are the Voigt-function and the associated dispersion profile, respectively, obtained by the convolution of a Maxwell distribution function (thermal broadening) with a Lorentzian profile, and v_A is the Doppler shift induced by LOS component of the macroscopic velocity, v_{LOS} :

$$v_A = \frac{v_{\text{LOS}}}{v_T} = \frac{\lambda_0 v_{\text{LOS}}}{c \Delta \lambda_D} = \frac{\nu_0 v_{\text{LOS}}}{c \Delta \nu_D}, \quad (5.23)$$

where under the assumption of a Maxwellian velocity distribution and single-atomic gas $v_T = \sqrt{3kT/m_0}$ (k is the Boltzmann constant, and m_0 is the mass of the atom).

Figure 5.2: The geometry of the scattering process. The vectors Ω' and Ω define the directions of the incident and scattered radiation, respectively. The unit vectors of polarization reference \hat{e}_a and \hat{e}_b are chosen in the way that $\hat{e}_a \perp \hat{e}_b$, $\hat{e}_a \times \hat{e}_b \parallel \Omega$, and \hat{e}_a lies in the plane defined by the vectors Ω and Ω' .

Let us consider an atomic system without hyperfine structure, and with energy levels characterized by the quantum numbers α representing the set of quantum numbers (electronic configuration, total orbital angular momentum, L , total electronic spin, S), J representing the total angular momentum, and magnetic quantum number M .

Substituting these quantum numbers in (5.16) leads to the subsequent replacements:

$$n \rightarrow \alpha_l J_l M_l, \quad m \rightarrow \alpha_u J_u M_u, \quad m' \rightarrow \alpha_u J_u M'_u, \quad (5.24)$$

where indexes "l" and "u" specify lower and upper levels between which electron transitions occur. Applying the Wigner-Eckart theorem to the spherical components of the dipole operator, and introducing the Einstein coefficient, A , for the magnetic dipole spontaneous transition $\alpha_u J_u \rightarrow \alpha_l J_l$, we get the spontaneous emission coefficients, $(\varepsilon_I, \varepsilon_Q, \varepsilon_U, \varepsilon_V) = (\varepsilon_0, \varepsilon_1, \varepsilon_2, \varepsilon_3)$, in the form:

$$\begin{aligned} \varepsilon_i(\nu, \mathbf{\Omega}) &= \frac{h\nu}{4\pi} N \sum_{\alpha_l J_l} \sum_{\alpha_u J_u} (2J_u + 1) A_{\alpha_u J_u \rightarrow \alpha_l J_l} \times \\ &\times \sum_{M_u M'_u M_l q q'} 3 \begin{pmatrix} J_u & J_l & 1 \\ -M_u & M_l & -q \end{pmatrix} \begin{pmatrix} J_u & J_l & 1 \\ -M'_u & M_l & -q' \end{pmatrix} \times \\ &\times \text{Re} [\mathcal{T}_{qq'}(i, \mathbf{\Omega}) \rho_{\alpha_u J_u}(M'_u, M_u) \Phi(\nu_{\alpha_u J_u M_u, \alpha_l J_l M_l} - \nu)] \end{aligned} \quad (5.25)$$

Here, $\mathcal{T}_{qq'}(i, \mathbf{\Omega})$ with $(q, q' = 0, \pm 1)$ is the reducible spherical tensor (Table A.1) specifying the geometry of the observer (Fig. 5.2), and Φ is the complex line profile centered at $\nu_0 = \nu_{\alpha_u J_u M_u, \alpha_l J_l M_l}$. It can be decomposed as follows:

$$\Phi(\nu_{ab} - \nu) = \phi(\nu_{ab} - \nu) + i\psi(\nu_{ab} - \nu), \quad (5.26)$$

where ϕ is the Voigt profile and ψ is the associated Faraday-Voigt dispersion function. The expressions in the matrix form in (5.25) are Wigner $3j$ -symbols.

5.3 Statistical-equilibrium equation

The density matrix element $\rho_{\alpha J}(M, M')$ can be found by solving the statistical-equilibrium equation, which involves any possible transition between the level of interest, (α, J) , and upper, (α_u, J_u) , and lower, (α_l, J_l) , levels:

$$\begin{aligned} \frac{d}{dt} \rho_{\alpha J}(M, M') &= -2\pi i \nu_L g_{\alpha J}(M - M') \rho_{\alpha J}(M, M') + \\ &+ \sum_{\alpha_l J_l} \sum_{M_l M'_l} \rho_{\alpha_l J_l}(M_l, M'_l) T_A(\alpha J M M', \alpha_l J_l M_l M'_l) + \\ - \sum_{\alpha_u J_u} \sum_{M_u M'_u} \rho_{\alpha_u J_u}(M_u, M'_u) &(T_E(\alpha J M M', \alpha_u J_u M_u M'_u) + T_S(\alpha J M M', \alpha_u J_u M_u M'_u)) - \\ &- \sum_{M''} \left[\rho_{\alpha J}(M, M'') (R_A(\alpha J M' M'') + R_E(\alpha J M'' M') + R_S(\alpha J M'' M')) + \right. \\ &\left. + \rho_{\alpha J}(M'', M') (R_A(\alpha J M'' M) + R_E(\alpha J M M'') + R_S(\alpha J M M'')) \right], \end{aligned} \quad (5.27)$$

Figure 5.3: Grotrian diagram for the radiative processes contributing to the evolution of the density matrix elements.

where T_A , T_E , and T_S are the coherence-transfer rates caused by absorption from lower levels, by spontaneous emission from upper levels and by stimulated emission from upper levels, respectively (Fig. 5.3). The density matrix elements are increased due to these processes. The quantities R_A , R_E , and R_S are the coherence-relaxation rates caused by absorption, spontaneous and stimulated emission, respectively. The density matrix elements are decreased due to these processes. The effect of stimulated radiation emission (described by T_S and R_S) can be neglected in the coronal plasma.

With help of the Wigner-Eckart theorem as for equations (5.16) and (5.25) one finds for the induced radiative processes:

$$T_A(\alpha J M M', \alpha_l J_l M_l M'_l) = (2J_l + 1) B_{\alpha_l J_l \rightarrow \alpha J} \times \\ \times 3(-1)^{M_l - M'_l} \sum_{qq'} \begin{pmatrix} J & J_l & 1 \\ -M & M_l & -q \end{pmatrix} \begin{pmatrix} J & J_l & 1 \\ -M' & M'_l & -q' \end{pmatrix} J_{qq'}(\nu_{\alpha J, \alpha_l J_l}), \quad (5.28)$$

$$R_A(\alpha J M M') = \frac{1}{2} \sum_{\alpha_u J_u} (2J + 1) B_{\alpha J \rightarrow \alpha_u J_u} \times \\ \times 3(-1)^{M - M'} \sum_{qq' M_u} \begin{pmatrix} J_u & J & 1 \\ -M_u & M & -q \end{pmatrix} \begin{pmatrix} J_u & J & 1 \\ -M_u & M' & -q' \end{pmatrix} J_{qq'}(\nu_{\alpha_u J_u, \alpha J}), \quad (5.29)$$

and for spontaneous radiative processes:

$$T_E(\alpha J M M', \alpha_u J_u M_u M'_u) = (2J_u + 1) A_{\alpha_u J_u \rightarrow \alpha J} \times \\ \times (-1)^{M_u - M'_u} \sum_q \begin{pmatrix} J_u & J & 1 \\ -M'_u & M' & -q \end{pmatrix} \begin{pmatrix} J_u & J & 1 \\ -M_u & M & -q \end{pmatrix}, \quad (5.30)$$

$$R_E(\alpha J M M') = \frac{1}{2} \delta_{MM'} \sum_{\alpha_l J_l} A_{\alpha J \rightarrow \alpha_l J_l}, \quad (5.31)$$

where

$$J_{qq'}(\nu) = \frac{1}{4\pi} \int \sum_{i=0}^3 \mathcal{T}_{qq'}(i, \Omega') S_i(\nu, \Omega') d\Omega' \quad (5.32)$$

is the reducible radiation field tensor. Here, $S_i(\nu, \Omega')$ is the Stokes vector of the incident radiation field propagating in the direction Ω' .

The rates in (5.27) are due to radiative processes. To include the collisional excitation and de-excitation, it is possible to modify (5.27) within the impact approximation (in which the duration of the collisional interaction is much smaller than the relaxation time due to radiation) by adding the collisional rates to the corresponding radiative ones (Lamb & ter Haar 1971).

5.4 The role of the collisions

There are two excitation mechanisms for ions in the corona: excitation by collisions and excitation by incident radiation coming from the photosphere.

Collisions (we consider only Fe XIII and Fe XIV, see figures 5.5 and 5.6) is the dominant excitation process in the lower corona near the photosphere (Sahal-Brechot 1974*b*). Due to the isotropic character of the collisions, they do not contribute to the polarization. Collisions can be divided in two types: those that are responsible for excitations between two different J -levels, and those that induce transitions between two magnetic sublevels within the same J -level (depolarizing collisions). The last type of collisions equilibrate the populations of the sublevels, a process which causes a depolarization of the emitted radiation.

Not only collisions for transitions within the line of interest must be taken into account while solving statistical equilibrium equation, but also collisions causing an excited configuration of an ion and subsequent cascades from the higher states must be considered (Pecker and Thomas 1962). The main mechanism for populating high excited levels of Fe XIV is the *electron excitation* from the ground state and the first excited levels (Petrini 1970).

On the other hand, depending on the impacting particles, collisions can be due to electron and proton impacts (the ion density in the corona is relatively low). *Proton impact* at coronal temperature can only excite transitions between sublevels of the ground configuration; excitations from the ground state to the excited configuration can be neglected (Landman 1975). For the Fe XIII and Fe XIV, depolarization rate caused by proton impact is very weak in comparison with electron excitation (Sahal-Brechot 1974*a*).

The numerical solution of the statistical equilibrium equation (5.27) for the density matrix elements was obtained by a number of authors (Sahal-Brechot 1974*a,b*, 1977; House 1977), who took into account the various collisional regimes listed above.

5.5 Photo-excitation

Beside collisional excitation, *photo-excitation* by radiation coming from the photosphere is another significant excitation process, especially at height above 1.4 solar radii (Raju et

al. 1991). This process is responsible for the resonance scattering and Hanle (in presence of a magnetic field) effects.

The photospheric radiation from the area bounded by the cone Ω comes to the point M situated at the distance R from the Sun's center (Fig. 5.4). The radiation density at the photospheric surface according black body assumption is

$$u(\nu) = \frac{8\pi h\nu^3}{c^3} \frac{1}{e^{h\nu/kT} - 1}, \quad (5.33)$$

with radiation temperature $T \approx 5770$ K (Allen 1973). The radiation density at the point M (Van de Hulst 1950) is

$$I(\nu) = Wu(\nu) = \frac{2A + B}{4}u(\nu), \quad (5.34)$$

where W is the limb-darkened total dilution. The terms A and B are defined through the center-limb darkening coefficient, q (Van de Hulst 1950):

$$A = (1 - q) \frac{2(1 - C) + \frac{1}{3}(1 - C^3)}{2} + q \frac{4D + E}{16}, \quad (5.35)$$

$$B = (1 - q) \left(\frac{2}{3} - C + \frac{1}{3}C^3 \right) + q \frac{4D - E}{8}, \quad (5.36)$$

where

$$D = 1 + \frac{C^2}{S} \ln \frac{C}{1 + S},$$

$$E = 1 + S^2 + \frac{C^4}{S} \ln \frac{C}{1 + S},$$

$$S = \sin \Omega = R_{\odot}/R, C = \cos \Omega$$

The radiation density, I , at the point M can be splitted into an isotropic component, I_i , and anisotropic one, I_a , ($I = I_i + I_a$):

$$I_i = \frac{3}{4}Bu_{\nu} = W_i u_{\nu}, \quad (5.37)$$

$$I_a = \frac{1}{2}(A - B)u_{\nu} = W_a u_{\nu}, \quad (5.38)$$

Figure 5.4: Anisotropy of the incident radiation field (Charvin 1965).

where W_i and W_a are isotropic and anisotropic dilution factors, respectively. The absorption rate of incident radiation can also be splitted into two parts expressed through the Einstein coefficient for stimulated transition, $B_{\alpha'J'M' \rightarrow \alpha JM}$ (Sahal-Brechot 1974b), an isotropic absorbtion rate

$$B_{\alpha'J'M' \rightarrow \alpha JM} \frac{\sigma_i}{3}, \quad (5.39)$$

and an anisotropic one, which creates the inequality of the populations of the Zeeman sublevels

$$B_{\alpha'J'M' \rightarrow \alpha JM} \frac{\sigma_a}{2} f(\Delta M, \Theta), \quad (5.40)$$

where $\Delta M = M - M'$, Θ is the angle between the quantization axis co-directed with \mathbf{B} and the direction of the incident radiation, $\mathbf{\Omega}'$, (figure 5.2), and

$$f(\Delta M, \Theta) = \begin{cases} \sin^2 \Theta, & \text{for } \Delta M = 0 \\ \frac{1 + \cos^2 \Theta}{2}, & \text{for } \Delta M = \pm 1. \end{cases} \quad (5.41)$$

5.6 Density matrix in irreducible tensor representation

The density matrix elements in (5.25) and (5.27) depend on the reference system. If the "new" reference system, S_{new} , is obtained from the "old" one, S_{old} , by the Euler rotation, R , then the density matrix transforms under the rule:

$$(\rho_{\alpha J}(M, M'))_{S_{new}} = \sum_{NN'} \mathcal{D}_{NM}^J(R)^* \mathcal{D}_{N'M'}^J(R) (\rho_{\alpha J}(N, N'))_{S_{old}}, \quad (5.42)$$

where $\mathcal{D}_{NM}^J(R)$ are rotation matrixes associated with the transformation R . This transformation involves the product of two rotation matrices. It is possible to construct linear combinations of these matrix elements in such way that the transformation R will involve only one rotation matrix. Then the density matrix will be described by spherical tensors of rank K (Landi 1984):

$$\rho_Q^K(\alpha J) = \sum_{MM'} (-1)^{J-M} \sqrt{2K+1} \begin{pmatrix} J & J' & K \\ M & -M' & -Q \end{pmatrix} \rho_{\alpha J}(M, M'), \quad (5.43)$$

$$(\rho_Q^K(\alpha J))_{S_{new}} = \sum_{Q'} \mathcal{D}_{Q'Q}^K(R)^* (\rho_{Q'}^K(\alpha J))_{S_{old}}, \quad (5.44)$$

where, due to the properties of the 3- j symbol, $K = 0, \dots, 2J$ and $Q = -K, \dots, K$. If the density matrix is diagonal ($M' = M$), i.e. in the no-coherence case, then, because of condition $M' - M = -Q$, $Q = 0$, a moment of the form ρ_0^K is a linear combination of populations. A moment of the form ρ_Q^K with $Q \neq 0$ is a linear combination of coherences between states characterized by projections of the angular momentum differing by Q .

Expressions similar to (5.43) and (5.44) can be written for the geometric tensor:

$$\mathcal{T}_Q^K(i, \mathbf{\Omega}) = \sum_{qq'} (-1)^{1+q} \sqrt{3(2K+1)} \begin{pmatrix} 1 & 1 & K \\ q & -q' & -Q \end{pmatrix} \mathcal{T}_{qq'}(i, \mathbf{\Omega}), \quad (5.45)$$

$$(\mathcal{T}_Q^K(i, \mathbf{\Omega}))_{S_{new}} = \sum_{Q'} \mathcal{D}_{Q'Q}^K(R) (\mathcal{T}_{Q'}^K(i, \mathbf{\Omega}))_{S_{old}}, \quad (5.46)$$

where $q, q' = 0, \pm 1$ denote spherical coordinate components, and due to the properties of the 3- j symbol $0 \leq K \leq 2$ and $Q = -K, \dots, K$.

For the $K = 0$ rank moment of the density matrix we have

$$\rho_0^0(\alpha J) = \frac{1}{\sqrt{2J+1}} \sum_M \rho_{\alpha J}(M, M), \quad (5.47)$$

which means that $\sqrt{2J+1}\rho_0^0(\alpha J)$ is the population of the level (αJ) . The multipole moments of rank $K = 1$ are connected with the average value of the angular momentum components. When these values are non-zero, there is a preferred direction in space, along which the atom is oriented. The multipole moments of rank $K = 2$ are connected with the average value of bilinear combinations of the angular momentum components. These multipole moments are called the *alignment* components of the density matrix, and they characterize the inequality of populations between π - and σ -components of the magnetic sublevels. The multipole moments of higher rank n are connected with the average values of polynomials of degree n in the angular momentum components.

5.7 The non-coherence approximation

There is the possibility of coherences between levels belonging to different atomic terms due to the level crossing. But, for Fe XIII and Fe XIV, the level crossing of different terms involves only highly excited states (never involves the ground one), which are excited and depopulated by isotropic collisional and spontaneous emission processes (Sahal-Brechot 1977). Therefore, the magnetic levels are equally and incoherently populated within a level (αJ) , such that

$$\rho(\alpha J M, \alpha' J' M') = \delta_{\alpha' \alpha} \delta_{J' J} \rho_{\alpha J}(M, M'). \quad (5.48)$$

Because of the low spontaneous transition probability, A , and the typical coronal magnetic field strength of ~ 10 G ($\omega_L \gg A$, strong field regime for Hanle-effect), any coherences between Zeeman sublevels are destroyed. Therefore, the off-diagonal components in the density matrix vanish:

$$\rho_{\alpha J}(M, M') = \delta_{M M'} \rho_{\alpha J}(M, M). \quad (5.49)$$

This approximation of completely diagonal density matrix leads to the restriction of the Q components in the spherical statistical tensors ($Q = 0$):

$$\rho_Q^K(\alpha J) = \delta_{Q0} \rho_0^K(\alpha J). \quad (5.50)$$

5.8 Weak field approximation

This section is devoted to considering the emission coefficient for the special case of the solar corona and based mainly on the investigation of Casini & Judge (1999) and references therein.

Because of high temperature ($\sim 10^6$ K) and relatively weak magnetic field strength (~ 10 G), thermal broadening of the line profile is much larger than Zeeman splitting.

Therefore it is possible to represent the Voigt profile in (5.25) by a Taylor expansion up to the first order in terms of the Zeeman splitting,

$$\delta\omega_{MM_0} = \omega_L(g_{\alpha_0 J}M - g_{\alpha_0 J_0}M_0). \quad (5.51)$$

The expansion about the center of gravity of the line yields: $\omega_c = \omega_{\alpha_0 J, \alpha_0 J_0}$:

$$\phi(\omega_{\alpha_0 J M, \alpha_0 J_0 M_0} - \omega) = \phi(\omega_c - \omega) + \phi'(\omega_c - \omega)\delta\omega_{MM_0}, \quad (5.52)$$

where $g_{\alpha_0 J}$ and $g_{\alpha_0 J_0}$ are the Lande factors of the levels $(\alpha_0 J)$ and $(\alpha_0 J_0)$, respectively. This representation suggests to divide the emission coefficients into two parts, zero- and first-order contribution ones:

$$\varepsilon_i(\omega, \mathbf{\Omega}) = \varepsilon_i^{(0)}(\omega, \mathbf{\Omega}) + \varepsilon_i^{(1)}(\omega, \mathbf{\Omega}), \quad (5.53)$$

$$\begin{aligned} \varepsilon_i^{(0)}(\omega, \mathbf{\Omega}) &= \frac{\hbar\omega}{4\pi} N(2J+1) A_{\alpha_0 J \rightarrow \alpha_0 J_0} \phi(\omega_c - \omega) \times \\ &\times \sum_K (-1)^{1+J+J_0} \sqrt{3} \left\{ \begin{matrix} 1 & 1 & K \\ J & J & J_0 \end{matrix} \right\} \rho_0^K(\alpha_0 J) \mathcal{T}_0^K(i, \mathbf{\Omega}), \end{aligned} \quad (5.54)$$

$$\begin{aligned} \varepsilon_i^{(1)}(\omega, \mathbf{\Omega}) &= \omega_L \frac{\hbar\omega}{4\pi} N(2J+1) A_{\alpha_0 J \rightarrow \alpha_0 J_0} \phi'(\omega_c - \omega) \times \\ &\times \sum_{KK'} \sqrt{3(2K+1)(2K'+1)} \begin{pmatrix} 1 & K & K' \\ 0 & 0 & 0 \end{pmatrix} \rho_0^K(\alpha_0 J) \mathcal{T}_0^{K'}(i, \mathbf{\Omega}) \times \\ &\times \left((-1)^{J-J_0} g_{\alpha_0 J} \sqrt{J(J+1)(2J+1)} \left\{ \begin{matrix} 1 & K & K' \\ J & J & J \end{matrix} \right\} \left\{ \begin{matrix} 1 & 1 & K' \\ J & J & J_0 \end{matrix} \right\} - \right. \\ &\quad \left. - g_{\alpha_0 J_0} \sqrt{J_0(J_0+1)(2J_0+1)} \left\{ \begin{matrix} 1 & K & K' \\ J_0 & J & 1 \\ J_0 & J & 1 \end{matrix} \right\} \right) \end{aligned} \quad (5.55)$$

Here, the two-row matrix form expressions in curved brackets are Wigner $6j$ -symbols, and the three-row matrix form expression in curved brackets is an Wigner $9j$ -symbol.

It is easy to find from (5.54) and (5.55) how different multiples of the density matrix contribute to the emission coefficients (Tables 5.1 and 5.2). Atomic orientation ($K = 1$) can be neglected in the solar corona because the exciting radiation from the photosphere is unpolarized. Also the contribution from the $K = 3$ moment can be neglected, because it has no observational effect. Thus, linear polarization can be produced only by atomic alignment ($K = 2$). And, total level population and atomic alignment also contribute to the circular polarization.

Finally, introducing the alignment factor

$$\sigma_Q^K(\alpha_0 J) = \frac{\rho_Q^K(\alpha_0 J)}{\rho_0^0(\alpha_0 J)}, \quad (5.56)$$

and the effective Lande factor for the transition $(\alpha_0 J) \rightarrow (\alpha_0 J_0)$ (Landi 1982)

$$\bar{g} = \frac{g_{\alpha_0 J} + g_{\alpha_0 J_0}}{2} + \frac{g_{\alpha_0 J} - g_{\alpha_0 J_0}}{4} (J(J+1) - J_0(J_0+1)), \quad (5.57)$$

Table 5.2: Contributing components, K , of the density matrix tensor, $\rho_0^K(\alpha_0 J)$, to the emission coefficients

we get expressions for the emission coefficients:

$$\varepsilon_I(\omega, \mathbf{\Omega}) = \varepsilon_0^{(0)}(\omega, \mathbf{\Omega}) = \frac{\hbar\omega}{4\pi} N_{\alpha_0 J} A \phi(\omega) \left(1 + D_{JJ_0} \sigma_0^2(\alpha_0 J) \frac{3 \cos^2 \theta - 1}{2\sqrt{2}} \right), \quad (5.58)$$

$$\varepsilon_Q(\omega, \mathbf{\Omega}) = \varepsilon_1^{(0)}(\omega, \mathbf{\Omega}) = \frac{\hbar\omega}{4\pi} N_{\alpha_0 J} A \phi(\omega) D_{JJ_0} \sigma_0^2(\alpha_0 J) \frac{3}{2\sqrt{2}} \cos 2\gamma \sin^2 \theta, \quad (5.59)$$

$$\varepsilon_U(\omega, \mathbf{\Omega}) = \varepsilon_2^{(0)}(\omega, \mathbf{\Omega}) = -\frac{\hbar\omega}{4\pi} N_{\alpha_0 J} A \phi(\omega) D_{JJ_0} \sigma_0^2(\alpha_0 J) \frac{3}{2\sqrt{2}} \sin 2\gamma \sin^2 \theta, \quad (5.60)$$

$$\varepsilon_V(\omega, \mathbf{\Omega}) = \varepsilon_3^{(1)}(\omega, \mathbf{\Omega}) = -\omega_L \frac{\hbar\omega}{4\pi} N_{\alpha_0 J} A \phi'(\omega) (\bar{g} + E_{JJ_0} \sigma_0^2(\alpha_0 J)) \cos \theta, \quad (5.61)$$

where

$$D_{JJ_0} = (-1)^{1+J+J_0} \sqrt{3(2J+1)} \begin{Bmatrix} 1 & 1 & 2 \\ J & J & J_0 \end{Bmatrix}, \quad (5.62)$$

$$E_{JJ_0} = 3\sqrt{2J+1} \times \left((-1)^{J-J_0} g_{\alpha_0 J} \sqrt{J(J+1)(2J+1)} \begin{Bmatrix} 1 & 2 & 1 \\ J & J & J \end{Bmatrix} \begin{Bmatrix} 1 & 1 & 1 \\ J & J & J_0 \end{Bmatrix} - g_{\alpha_0 J_0} \sqrt{J_0(J_0+1)(2J_0+1)} \begin{Bmatrix} 1 & 2 & 1 \\ J_0 & J & 1 \\ J_0 & J & 1 \end{Bmatrix} \right). \quad (5.63)$$

Here $N_{\alpha_0 J}$ is the population density of the excited level, and A the Einstein spontaneous coefficient for the $(\alpha_0 J_0) \rightarrow (\alpha_0 J)$ transition.

We can clearly see from the (5.58) that total emission vector, ε_I , depends on the LOS direction, and how strong this dependence is defined by the alignment factor σ_0^2 . When $\sigma_0^2(\alpha_0 J)$ is much less than unity (for example, $\sigma_0^2(\alpha_0 J) \sim 10^{-2}$ for the He I D3 line), we can neglect the directional dependence of the total emission coefficient.

5.9 Magnetograph formula

From equations (5.58)-(5.61) one can see that total emission and Stokes- V component are connected via magnetograph formula:

$$\varepsilon_V(\omega, \mathbf{\Omega}) = k \bar{g} \omega_L \cos \theta \frac{d\varepsilon_I(\omega, \mathbf{\Omega})}{d\omega}. \quad (5.64)$$

The effect of the alignment is represented here by the coefficient

$$k = \frac{1 + E_{JJ_0} \sigma_0^2(\alpha_0 J) / g}{1 + 2^{-3/2} D_{JJ_0} \sigma_0^2(\alpha_0 J) (3 \cos^2 \theta - 1)}. \quad (5.65)$$

Again, like in the case for the total emissivity, this coefficient, k , depends on the alignment factor σ_0^2 . Integrating (5.64) along some LOS we get

$$V(\omega, \mathbf{\Omega}) = \int \varepsilon_V(\omega, \mathbf{\Omega}) dl = \int k \bar{g} \omega_L \cos \theta \frac{d\varepsilon_I(\omega, \mathbf{\Omega})}{d\omega} dl \quad (5.66)$$

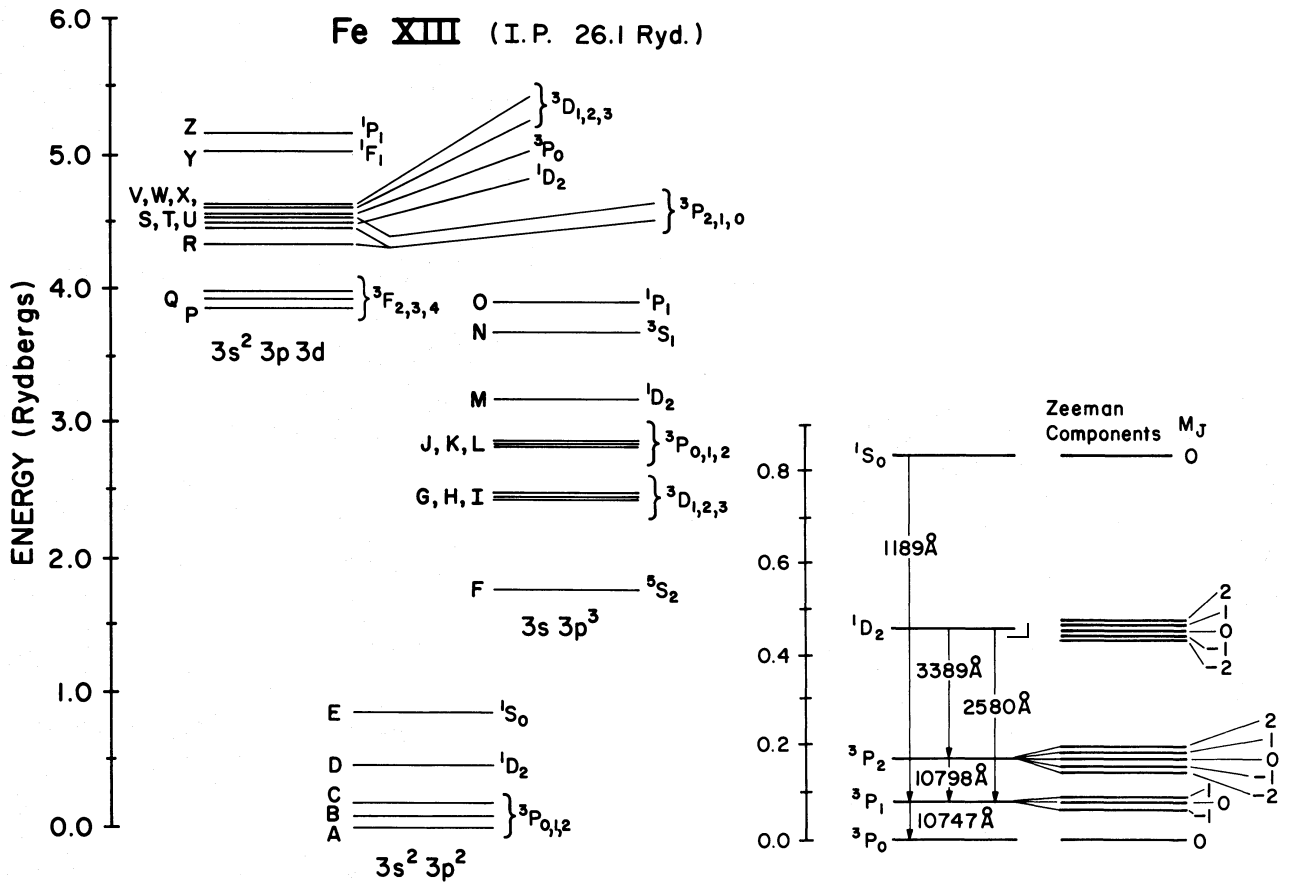

Figure 5.5: Energy levels of Fe XIII. The Zeeman splitting is only shown for $3s^2 3p^2$ term (House 1977).

Here, the derivative of the total emission, I , which is a quantity that can independently be measured as a LOS integral:

$$\frac{dI(\omega, \Omega)}{d\omega} = \int \left(\frac{d\varepsilon_I(\omega, \Omega)}{d\omega} \right) dl. \quad (5.67)$$

The nice property of using the magnetograph formula, in contrary to the Faraday-effect, is that it is not necessary to know the distribution of the ion density and temperature over the corona. All coefficients in (5.64) are either intrinsically atomic quantities which depend only on the type of ion, while $d\varepsilon_I(\omega, \Omega)/d\omega$ can be obtained from a scalar tomographic inversion of the observations (5.67).

5.10 Emission line 10747 Å of the Fe XIII

The coronal emission line 10747 Å was first observed by B. Lyot (Lyot 1939) in 1936. Later, the line was identified by B. Edlén (1943) as the ${}^3P_1 - {}^3P_0$ transition of the ground configuration of the Fe XIII ion (Fig. 5.5). First measurements of the polarization of the line were made by Eddy and Malville (1967) during the 1965 eclipse. The observations showed that the linear polarization was predominantly radially oriented and the degree

of polarization increased with distance from the Sun. Later, the Coronal Emission Line Polarimeter (KELP) constructed by the High Altitude Observatory (HAO) provided more precise measurements (Querfeld & Elmore 1976; Querfeld & Smartt 1984). The theory for the interpretation of the observation was also developed by Charvin (1965), House (1974, 1977), Querfeld (1982).

Since the line is infrared it is very promising for the derivation of the magnetic field by the longitudinal Zeeman-effect, because the Zeeman splitting is proportional to the second power of the wavelength, but the thermal broadening increases only with the first power. Moreover, this line has lower and upper states $J_l = 0$ and $J_u = 1$, respectively. The upper state therefore splits only into three magnetic sublevels which simplifies the calculations.

As the levels of interest belong to the same ground state, we can omit α in the following notations for the density matrix. Taking into account that $J_l = 0$ and $J_u = 1$, we write for the sublevels with $M = \pm 1$:

$$\rho_1(1) = \rho_1(-1) = \rho_1(\pm 1) \equiv \rho_{\alpha J_u}(\pm 1),$$

and for the sublevel with $M = 0$

$$\rho_1(0) \equiv \rho_{\alpha J_u}(0).$$

The emission coefficients (5.25) into space angle Ω can be integrated over the line profile and are then after (Querfeld 1982)

$$\begin{pmatrix} \varepsilon_I(\Omega) \\ \varepsilon_Q(\Omega) \\ \varepsilon_U(\Omega) \\ \varepsilon_V(\Omega) \end{pmatrix} = \frac{3\hbar\omega A}{8\pi} \begin{pmatrix} \rho_1(\pm 1)(1 + \cos^2 \theta) + \rho_1(0) \sin^2 \theta \\ [\rho_1(\pm 1) - \rho_1(0)] \sin^2 \theta \cos 2\alpha \\ [\rho_1(\pm 1) - \rho_1(0)] \sin^2 \theta \sin 2\alpha \\ 0 \end{pmatrix}. \quad (5.68)$$

Here α now denotes the angle between the local radius vector and the observed polarization projected on the plane of the sky (POS) (Fig. 5.2). Let us denote the sum and difference of the populations through

$$\Sigma = [2\rho_1(\pm 1) + \rho_1(0)], \quad (5.69)$$

$$\Delta = [\rho_1(\pm 1) - \rho_1(0)], \quad (5.70)$$

Then the emission coefficients are

$$\begin{pmatrix} \varepsilon_I(\Omega) \\ \varepsilon_Q(\Omega) \\ \varepsilon_U(\Omega) \end{pmatrix} = \frac{\hbar\omega A}{8\pi} \begin{pmatrix} 2\Sigma + \Delta (3 \cos^2 \theta - 1) \\ 3\Delta \sin^2 \theta \cos 2\alpha \\ 3\Delta \sin^2 \theta \sin 2\alpha \end{pmatrix}. \quad (5.71)$$

Solving the statistical equilibrium equations (5.27), one finds that Δ is proportional to $(3 \cos^2 \Theta - 1)$ where Θ is the angle between the direction of the radius vector from the center of the Sun and the magnetic field vector (Charvin 1965; Sahal-Brechot 1974a, 1977; House 1977). The Σ and Δ can be decomposed in the manner (Querfeld 1982):

$$\Sigma = \frac{\Sigma}{\rho_0(0)} \frac{\rho_0(0)}{N_{\text{FeXIII}}} \frac{N_{\text{FeXIII}}}{N_{\text{Fe}}} \frac{N_{\text{H}}}{N_{\text{H}}} \frac{N_{\text{H}}}{N_{\text{e}}} N_{\text{e}} = \Sigma' \rho_0'(0) N_i A_{\text{Fe}} \frac{N_{\text{H}}}{N_{\text{e}}} N_{\text{e}}, \quad (5.72)$$

$$\Delta = \frac{\Delta}{\rho_0(0)} \frac{\rho_0(0)}{N_{\text{FeXIII}}} \frac{N_{\text{FeXIII}}}{N_{\text{Fe}}} \frac{N_{\text{H}}}{N_{\text{H}}} \frac{N_e}{N_e} = \Delta' (3 \cos^2 \Theta - 1) \rho'_0(0) N_i A_{\text{Fe}} \frac{N_{\text{H}}}{N_e} N_e \quad (5.73)$$

where $\rho_0(0)$ is the population of the level $J = 0$, and $\rho'_0(0) = \rho_0(0)/N_{\text{FeXIII}}$ is the population relative to the total Fe XIII number density, N_{FeXIII} . the symbol N_{Fe} is the iron number density, N_{H} the proton number density, and N_e the electron density. The iron abundance $A_{\text{Fe}} = N_{\text{Fe}}/N_{\text{H}}$ is assumed to be $7.08 \cdot 10^{-5}$ (Withbroe 1971). The value of the ionization equilibrium $N_i = N_{\text{FeXIII}}/N_{\text{Fe}}$ is 0.239 at temperature $T = 1.8 \cdot 10^6$ K (Jacobs et al. 1977). The helium abundance is assumed to be 10%, and so the proton abundance N_{H}/N_e is 0.8.

The dependence of the population difference Δ on the angle Θ is the so called van Vleck effect (van Vleck 1925). The van Vleck effect completely depolarizes the scattered radiation when $\Theta^* = \arccos(1/\sqrt{3}) \approx 54.7^\circ$ (the van Vleck angle). After the van Vleck angle is passed (i.e. for $\Theta > \Theta^*$), the Stokes vectors Q and U change sign, which means that the plane of polarization now is perpendicular to the magnetic field.

To calculate the quantities Σ' , Δ' and $\rho'_0(0)$ Querfeld (1982) reduced the House (1977) statistical equilibrium equations to a set of 15 equations for all of the ground term sublevels by removing the explicit calculation of the 91 excited term sublevels. This set of 15 equations was further reduced to 10 equations because of the alignment property $\rho_1(M) = \rho_1(-M)$. Solving this reduced system of equations, he approximated expressions for the Σ' , Δ' and $\rho'_0(0)$ by the fits:

$$\begin{aligned} & \rho'_0(0) \frac{h\nu A R_\odot^2}{8\pi I_0} N_i A_{\text{Fe}} \frac{N_{\text{H}}}{N_e} = \\ & = 250(1 - 0.360W + 0.0588W^2) \frac{1 + (0.00802 + 0.00214 \log T_6) N_8}{1 + (0.0831 + 0.0394 \log T_6) N_8} \end{aligned} \quad (5.74)$$

$$\Sigma' = 0.360W + \frac{(0.0464 + 0.01013 \log T_6) N_8}{1 + 0.0178N_8} \quad (5.75)$$

$$\Delta' = 0.0900W_a \frac{1 - (0.01172 - 0.00755 \log T_6) N_8}{1 + 0.0819N_8}, \quad (5.76)$$

where

$$1 \leq T_6 \leq 3, \quad N_8 \leq 100. \quad (5.77)$$

Here, W and W_a are the limb-darkened total and anisotropy dilution factors as defined by (5.34) and (5.34), with limb-darkening function $q = 0.33$ (Allen 1973). In the above equations T_6 is the temperature in units of 10^6 K, N_8 is the electron density in units of 10^8 cm^{-3} , and I_0 is the central disk brightness.

5.11 Emission line 5303 Å of the Fe XIV

The 5303 Å line of Fe XIV (green line) is the brightest forbidden emission line in the visible coronal spectrum. The line was discovered by Young and Harkness during the 1869 total solar eclipse, and identified later by Grotrian (1939) and Edlen (1943). The emissivity of the green line has a maximum at $\sim 2 \cdot 10^6$ K (Esser et al. 1995; Guhathakurta et al. 1992). The excitation mechanism is mainly collisional up to $\sim 1.4R_\odot$, while in the higher regions, the radiative excitation is dominant (Raju 1991). The line was intensively

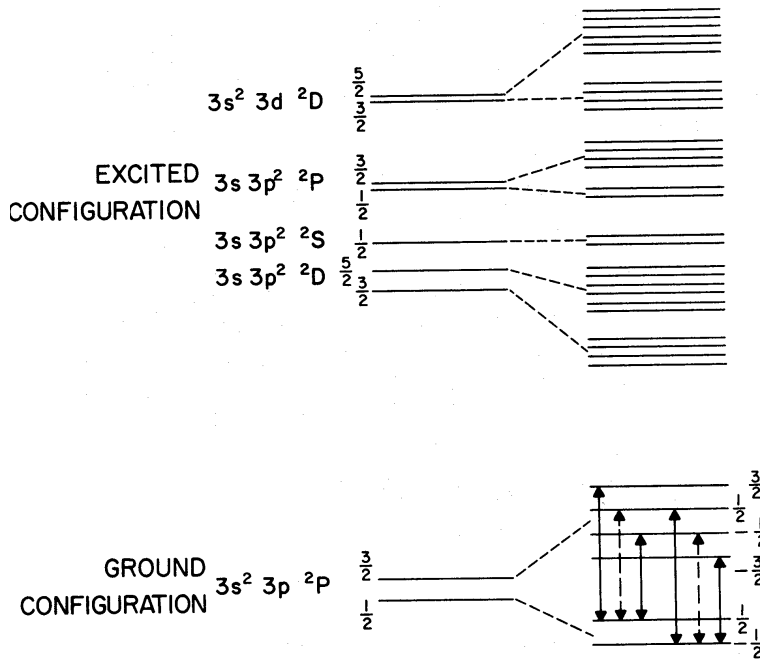

Figure 5.6: Energy levels of Fe XIV (House 1982).

observed by the LASCO coronagraph on board the SOHO spacecraft (Brueckner et al. 1995; Schwenn et al. 1997; Inhester et al. 1999).

The observed green line emission is closely related to the underlying photospheric magnetic field. The brightest emissions come from active regions with strong magnetic field. A prominent feature at low solar activity are high-altitude streamers which occur in the regions where the magnetic flux from large active regions is connected to the high-latitude unipolar fields. The global emission pattern rotates quasi-rigidly at the rate of the dominant active regions.

A current-free magnetic field model does not always properly reflect the observed coronal structures, particularly near prominences and in the boundary region between open and closed magnetic fields (Wang et al. 1997).

One of the first polarization observation of the line was made by Mogilevskij et al. (1960) during the eclipse of June 30, 1954. Later, a coronameter especially designed to measure the green line polarization has been built at Pic-du-Midi observatory (Charvin 1971; Arnaud 1982a). The obtained polarization maps often display a large-scale homogeneous structure that is surprising because of the complex density structure of the corona (Arnaud 1982b).

As the levels of the line emission belong to the same ground configuration (Fig. 5.6), we can omit α in the following notations for the density matrix, and taking into account that $J_l = \frac{1}{2}$ and $J_u = \frac{3}{2}$, we can write for the magnetic sublevels $M = \pm\frac{1}{2}$ of the lower state $J_l = \frac{1}{2}$

$$\rho_{\frac{1}{2}}(-\frac{1}{2}) = \rho_{\frac{1}{2}}(\frac{1}{2}) = \rho_{\frac{1}{2}}(\pm\frac{1}{2}) \equiv \rho_{\alpha J_l}(\pm\frac{1}{2}), \quad (5.78)$$

and for the magnetic sublevels $M = \pm\frac{1}{2}, \pm\frac{3}{2}$ of the upper state $J_u = \frac{3}{2}$

$$\rho_{\frac{3}{2}}(-\frac{1}{2}) = \rho_{\frac{3}{2}}(\frac{1}{2}) = \rho_{\frac{3}{2}}(\pm\frac{1}{2}) \equiv \rho_{\alpha J_u}(\pm\frac{1}{2}), \quad (5.79)$$

$$\rho_{\frac{3}{2}}(-\frac{3}{2}) = \rho_{\frac{3}{2}}(\frac{3}{2}) = \rho_{\frac{3}{2}}(\pm\frac{3}{2}) \equiv \rho_{\alpha J_u}(\pm\frac{3}{2}). \quad (5.80)$$

The sum and difference of the magnetic sublevel belonging to the upper level can be expressed as:

$$\Sigma = 2 \left(\rho_{\frac{3}{2}}(\pm\frac{3}{2}) + \rho_{\frac{3}{2}}(\pm\frac{1}{2}) \right), \quad (5.81)$$

$$\Delta = 2 \left(\rho_{\frac{3}{2}}(\pm\frac{3}{2}) - \rho_{\frac{3}{2}}(\pm\frac{1}{2}) \right). \quad (5.82)$$

Then the emission coefficients integrated over line profile are (House et al. 1982)

$$\begin{pmatrix} \varepsilon_I(\Omega) \\ \varepsilon_Q(\Omega) \\ \varepsilon_U(\Omega) \end{pmatrix} = \frac{\hbar\omega A}{8\pi} \begin{pmatrix} 4\Sigma + \Delta (3 \cos^2 \theta - 1) \\ 3\Delta \sin^2 \theta \cos 2\alpha \\ 3\Delta \sin^2 \theta \sin 2\alpha \end{pmatrix}. \quad (5.83)$$

Introducing the relative sum and difference populations Σ' and Δ' like in Sec. 5.10, we may write

$$\Sigma = N\Sigma', \quad (5.84)$$

$$\Delta = N\Delta'(3 \cos^2 \Theta - 1), \quad (5.85)$$

where N is the total population of all sublevels in the ground configuration, and the equation (5.83) can be rewritten as

$$\begin{pmatrix} \varepsilon_I(\Omega) \\ \varepsilon_Q(\Omega) \\ \varepsilon_U(\Omega) \end{pmatrix} = \frac{\hbar\omega A}{8\pi} N \begin{pmatrix} 4\Sigma' + \Delta' (3 \cos^2 \theta - 1) (3 \cos^2 \Theta - 1) \\ 3\Delta' (3 \cos^2 \Theta - 1) \sin^2 \theta \cos 2\alpha \\ 3\Delta' (3 \cos^2 \Theta - 1) \sin^2 \theta \sin 2\alpha \end{pmatrix}. \quad (5.86)$$

For calculating the density matrix elements, House (1974) and Sahal-Brechot (1974b) used a nine level (34 sublevel) model of the Fe XIV (Fig. 5.6), i.e., the statistical equilibrium condition involves 34 equations. To reduce the calculation time, House et al. (1982) reduced these 34 equations to a set of six equations by reducing the equations which couple the ground to excited configurations to an equivalent set of indirect rates coupling only ground configuration sublevels. Using the alignment assumption $\rho_{\alpha J}(M) = \rho_{\alpha J}(-M)$, they further reduced the remaining six equations to three. These three equations give expressions for Σ' and Δ' :

$$\Sigma' = \frac{W + 0.6585(1 - 0.0697T_6)N_8}{37.26 + W + 1.0295(1 - 0.0697T_6)N_8}, \quad (5.87)$$

$$\Delta' = \frac{W_a(1 - \Sigma')}{149.04 + (4.7420 - 0.1340T_6)N_8}, \quad (5.88)$$

where W and W_a are the total and anisotropic dilution factors, respectively, which can be calculated using Allen's (1973) limb darkening function with $q = 0.62$ (see Sec. 5.5). In these formulae, T_6 is the electron temperature in units of 10^6 K, and N_8 is the electron density in units of 10^8 cm^{-3} .

The total population of all the sublevels in the ground configuration, N , can be assumed to be equal the total Fe XIV population, since the total population in the excited configuration is $\sim 10^{-9}N$. So, using the same notations like in Section 5.10, we have

$$N = N_{\text{FeXIV}} = N_{\text{H}}A_{\text{Fe}} \frac{N_{\text{FeXIV}}}{N_{\text{Fe}}}. \quad (5.89)$$

5.12 Influence of the alignment factor

The total intensity (Stokes- I) in equations (5.86), (5.71) and (5.58) is composed of two terms. The first, proportional to Σ' , is isotropic while the second, proportional to Δ' , depends on the angles θ and Θ which the local magnetic field forms with the LOS direction and the local radius vector, respectively. A measure of how much the Stokes- I component deviates from isotropy is therefore given by the ratios:

$$\eta_{\text{FeXIII}} = \frac{\Delta'_{\text{FeXIII}}}{2\Sigma'_{\text{FeXIII}}} \text{ for } 10747 \text{ \AA line of Fe XIII}, \quad (5.90)$$

$$\eta_{\text{FeXIV}} = \frac{\Delta'_{\text{FeXIV}}}{4\Sigma'_{\text{FeXIV}}} \text{ for } 5303 \text{ \AA line of Fe XIV}. \quad (5.91)$$

The population difference Δ is proportional to the alignment factor (5.56) which is different for different lines and varies with density and temperature.

Taking the coronal electron density distribution from Newkirk (1970),

$$N_e(r) = (755r^{-5.353} - 168r^{-14.738} + 103800r^{-20.446}) \cdot 10^{11} \text{ cm}^{-3}, \quad (5.92)$$

where distance r is in solar radii, and using (5.74)-(5.76) and (5.87)-(5.88), we can calculate the ratios (5.90) and (5.91) as functions of radial distance, r , and temperature, T (Fig. 5.7).

To estimate the influence of the alignment factor in the total intensity, it is necessary to multiply the ratio η with the term depending on the magnetic field configuration, $V(\theta)V(\Theta) = (3 \cos^2 \theta - 1)(3 \cos^2 \Theta - 1)$. Theoretically, $V(\theta)V(\Theta)$ varies within

Figure 5.7: The ratios η_{FeXIII} (a) and η_{FeXIV} (b) for the 10747 Å and 5303 Å lines of Fe XIII and Fe XIV, respectively.

$-2 \leq V(\theta)V(\Theta) \leq 4$. But because of central occulter (Sun's disk) we have a limitation in the possible LOS directions, and, therefore, $-2 < V(\theta)V(\Theta) \lesssim 3.2$ for $R_{\odot} < r \leq 2R_{\odot}$. So, depending on the magnetic field configuration, location of the observed region and LOS direction, the maximal contribution of the anisotropic part to the total intensity is less than 32 and 13 % for the 10747 and 5303 Å lines, respectively. This is the maximum error of a simplified emission coefficient ε_I for Stokes- I which omits the anisotropic part of the emission. The advantage of this simplified emission ε_I is that it depends linearly on $N\Sigma'$ with a space-independent coefficient. Hence, $N\Sigma'$ can be obtained with this approximation from a straightforward scalar tomography inversion of the Stokes- I data.

6 Test simulations

6.1 The coordinate system

The center of the main reference system is situated in the center of the sun. The z -axis is parallel to the sun's rotation axis and directed to the north pole. The x -axis is connected to some fixed point on the solar equator, and the y -axis is chosen in a way giving a right-handed reference system. The investigated volume is bounded by two spheres with radial distances R_\odot and $R_{\text{out}} = 2R_\odot$. A rectangular discretization grid was chosen which has equidistant spacing and is aligned with the x , y and z coordinate axes (Fig. 6.1). The cells that cross the inner (the sun's surface) and outer spherical boundaries of the investigated volume are cut by these boundaries, i.e. they are not cubic. Within each cell of the grid, the magnetic field is assumed to be constant. The cells are numbered, and it is possible to create a column-matrix \mathbf{X} the elements of which are the components of the magnetic field vector, $\mathbf{B} = B^x \hat{\mathbf{e}}_x + B^y \hat{\mathbf{e}}_y + B^z \hat{\mathbf{e}}_z$, at the cell's center of gravity:

$$X_{3i-2} = B_i^x, \quad X_{3i-1} = B_i^y, \quad X_{3i} = B_i^z. \quad (6.1)$$

6.2 Discretization of the divergence operator

To calculate the regularization term F_{reg} in (3.13), the Gauss-Ostrogradskii theorem was used, which states that the flux of some vector field through a closed surface equals the integral of the divergence of the field over the volume bounded by this surface. So, as-

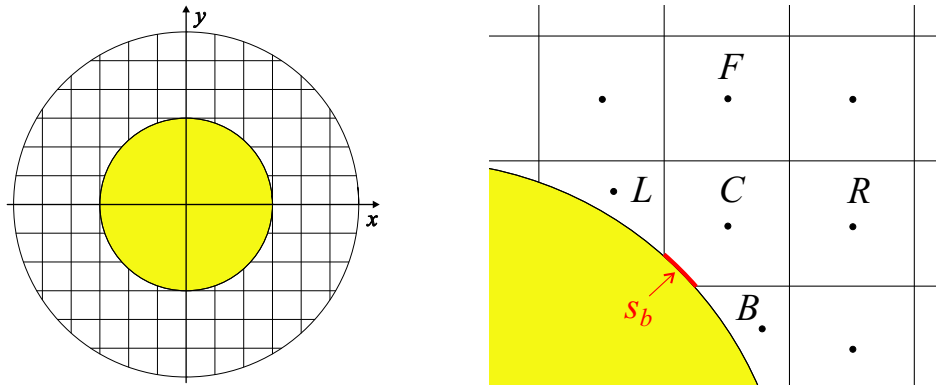

Figure 6.1: The example of $12 \times 12 \times 12$ grid: cross section by the plane $z = 0$. Yellow area is the Sun.

suming that $\nabla \cdot \mathbf{B}$ is constant within each cell i , one obtains

$$\begin{aligned} \int_{\text{Corona}} (\nabla \cdot \mathbf{B})^2 dV &= \sum_{\text{All cells } i} \left[\int_{i\text{-th cell}} (\nabla \cdot \mathbf{B})^2 dV \right] = \\ &= \sum_{\text{All cells } i} \left[\left(\frac{\Phi_i}{V_i} \right)^2 \int_{i\text{-th cell}} dV \right] = \sum_{\text{All cells } i} \frac{\Phi_i^2}{V_i}, \end{aligned} \quad (6.2)$$

where Φ_i is the net magnetic flux out of the i -th cell, and V_i is the volume of the i -th cell. The V_i has the character of weighting coefficient, and it was dropped to simplify the calculations. Let us denote the i -th cell as "C"(central) and the surrounding cells as "L"(left), "R"(right), "F"(forward), "B"(backward), "U"(upper) and "D"(down) as shown at Fig. 6.1b (upper and lower cells are not shown). The cell may be cut by the spherical boundary surface. The cut area is denoted by S_b . Then, a formula for the calculation of the net flux out of i -th cell used in simulations can be derived from the linearly interpolated field on each cell face, i.e.

$$\begin{aligned} \Phi_i &= -\frac{B_L^x + B_C^x}{2} S_L + \frac{B_R^x + B_C^x}{2} S_R + \frac{B_F^y + B_C^y}{2} S_F - \frac{B_B^y + B_C^y}{2} S_B + \\ &\quad + \frac{B_U^z + B_C^z}{2} S_U - \frac{B_D^z + B_C^z}{2} S_D - \Phi_b, \end{aligned} \quad (6.3)$$

where S_L, S_R, S_F, S_B, S_U , and S_D are the areas of the faces common for the i -th cell and respective surrounding cells. If i -th cell intersects with the boundary surface, Φ_b is the flux out of the boundary area S_b (see Fig. 6.1), otherwise $\Phi_b = 0$. If S_b lies on the solar surface, the representative field is directly taken from the surface boundary data. The flux through the outer spherical boundary is assumed to be unknown and, therefore, we do not include the flux through the cells cut by the outer boundary in the sum (6.2), but the magnetic field vectors defined at these cells are used to define the fluxes through the other cells. This makes the problem more ill-posed. For late practical calculations, especially when the outer boundary sphere exceeds $2R_\odot$, the field on the outer sphere could be constrained to be radial. So, by defining the fluxes in this manner, we can write the regularization term in the matrix form (3.14).

In the simulations showed below it was used a rectangular grid of $40 \times 40 \times 40$ cells.

6.3 Discretization of the line-of-sight integration

Although every image pixel has a finite size, we approximate them by a point at the center of the physical pixel. So, the LOS volume from which the emission is projected onto the pixel is approximated by a line. This approximation is commonly used in many tomographic applications (Natterer 1986). It does not cause a big error in the case when the pixel size in the image is less than the cell size chosen for the grid. The distribution of the pixels in one image is set to be uniform with coordinates (figure 3.1):

$$\begin{aligned} x_p &= -R_{\text{out}} + \Delta x/2 + (i - 1) \cdot \Delta x, \\ y_p &= -R_{\text{out}} + \Delta y/2 + (j - 1) \cdot \Delta y, \end{aligned} \quad (6.4)$$

where i and j are integer numbers, Δx and Δy are the cell sizes in x and y directions, respectively, and $R_{\odot}^2 < x_p^2 + y_p^2 < R_{\text{out}}^2$.

The observations are assumed to be made from the Earth at a time when the Sun's rotation axis is perpendicular to the view direction ($\theta = \pi/2$ in the Fig. 3.1), and due to the smallness of the variation of θ during one solar rotation, we assume that the angle is constant during one solar rotation. The angle ϕ varies in the simulations from 0 to 360° in steps of 10° .

The minimizing function in the case of the longitudinal Zeeman effect data can be written in the matrix form (see eq. (3.12) and (3.14)) as follows:

$$F = \mu \cdot F_{\text{tomo}} + F_{\text{reg}} = \mu \cdot |\mathbf{A} \cdot \mathbf{X} - \mathbf{Y}|^2 + |\mathbf{G} \cdot \mathbf{X} - \mathbf{B}|^2. \quad (6.5)$$

We have placed the regularization parameter at the tomographic term F_{tomo} but not at the regularization term. This only affects the value of the resulting function F but not its behavior. The matrices here have a similar meaning as in (3.12) and (3.14). The components X_{3j-k} ($k = 2, 1, 0$) of the column-vector \mathbf{X} contains the components of the vector \mathbf{B} in the j -cell, and y_i is the data value for the i -th ray, where the index $i = 1, \dots, m$ counts the view angles, ϕ and θ , and the pixel position (x_p, y_p) . The matrix element $a_{i,3j-k}$ represents the projection of the volume element j along the LOS related to the pixel i , multiplied with some distance depended coefficient $k(r)$ and with the components of the unit vector along the LOS. The coefficient $k(r)$ is assumed to be constant within a cell. In the case of Faraday-effect data, the coefficient $k(r)$ is the electron density. In the case of Zeeman-effect data, the coefficient $k(r)$ is defined from the magnetograph formula (5.64), when the alignment factor, σ_0^2 (5.56), is set to zero. The radial dependence of $k(r)$ in this case does not principally differ from the radial dependence of the electron density. "Principally" means that their power exponents do not differ by more than one unit. Therefore, to show the possibility of the reconstruction method we assumed that the radial dependence of the coefficient $k(r)$ is the same like for the electron density defined in (5.92). Here, we assumed that the alignment factor is set to zero. Otherwise, the minimizing function cannot be expressed in the linear form (6.5), but must be derived by using the general form (5.64) of the magnetograph formula.

The number of the projections was set to 36, and they were equispaced in the all range of angles from 0 to 2π .

6.4 Magnetic field configuration for the test calculations

The model field configuration is a dipole, with the dipole axis being inclined in the x - z plane by 10° with respect to the Sun's rotation axis (z -axis). We added to the main dipole field a perturbation which is induced by a circular current in the x - z -plane with radius $R_{\odot}/2$ and center situated in the point $(R_{\odot}/2; 0; 0)$ (see Fig. A.2). This perturbation adds a non-potential component to the test field which cannot be reconstructed by extrapolation methods from the surface data. The perturbation also modifies the axially symmetric unperturbed model to be a non-axially-symmetric model. The reconstruction of this perturbation with tomography data therefore represents a critical test of our method.

In the calculations below, we used arbitrary units for \mathbf{B} . At the point $(1.4R_{\odot}; 0; 0)$ close to the perturbing current, the field strength of the main dipole component in the arbitrary units is 3.5, while the strength of the perturbing field component at this point, one cell spacing away from the perturbing current, is 2.8.

6.5 Reconstruction based on the Zeeman-effect data

From the model test field configuration the model data were calculated by a simple forward step. Random noise was added to the tomography data and surface magnetic field data at the photosphere (inner boundary condition) by multiplying the exact data and boundary conditions by $(1 + \delta)$, where δ is a uniformly distributed random number in the range $(-\varepsilon_n; +\varepsilon_n)$. The simulations were done with a noise level $\varepsilon_n = 0.05$, i.e. 5%.

To minimize the function (6.5), the conjugate gradient method was used. The potential field reconstruction described in the section A.1 was used as initial field configuration for the iterations (Fig. A.3). The list of performed test reconstructions is shown in Table A.2. In the further discussions, we will use the notations in this table for the performed reconstructions.

Due to the very strong radial dependence of the electron density, the signal in a ray which passes the Sun at a greater distance is much less than for closer rays. Therefore, the contribution from these distant rays to the minimizing function is small. To increase the contribution of signals from distant rays, and to stabilize their numerical reconstruction, the data of pixel $(x_p; y_p)$ was weighted with a function

$$w_{sc}(r_p) = \frac{r_p^4}{n_e(r_p)}, \quad (6.6)$$

where $r_p = \sqrt{x_p^2 + y_p^2}$.

During the minimization procedure, two questions arose: How to choose the value of the regularization parameter μ , and What is the optimal number of iterations. These problems may be solved by using the *L-curve* method (Section 2.4). The Fig. 6.2 shows the evolution of the logarithm of the data error, F_{tomo} , versus the logarithm of the regularization term, F_{reg} , during the iterations for different values of μ . A critical value for F_{tomo} is the data noise level $\mathcal{E}_{\text{tomo}}$, which in this example was calculated as

$$\mathcal{E}_{\text{tomo}} = |\mathbf{Y}_n - \mathbf{Y}_0|^2, \quad (6.7)$$

where \mathbf{Y}_n and \mathbf{Y}_0 are the tomography data with and without noise, respectively. In Fig. 6.2, $\ln \mathcal{E}_{\text{tomo}}$ is shown as a horizontal dashed line. The difference in the (6.7) is just random noise with known distribution function which is added to the noiseless data \mathbf{Y}_0 . For real problems, \mathbf{Y}_0 is not known, and $\mathcal{E}_{\text{tomo}}$ may be estimated from the instrument noise level. In the diagram $\ln F_{\text{tomo}}$ versus $\ln F_{\text{reg}}$, the iterations asymptotically converge to the L-curve. Fig. 6.4 shows that the solutions obtained after 5000 iterations lie very close to the L-curve. The corner of the L-curve however lies much below the data noise level $\mathcal{E}_{\text{tomo}}$. In this case the value of μ found from the L-curve is not optimal (Hansen 1993; Hanke 1996).

All evolution lines in the Fig. 6.2 cross below the data noise level $\mathcal{E}_{\text{tomo}}$. However, when the error F_{tomo} becomes smaller than $\mathcal{E}_{\text{tomo}}$, we begin to fit our reconstruction to the noise in the data. For ill-conditioned problems, this results in a strongly amplified noise in the reconstruction model. We therefore stop the iteration when $F_{\text{tomo}} \cong \mathcal{E}_{\text{tomo}}$. So, this criterion (Mozorov's criterion) determines the number of iterations in our case to be approximately 47 for values of μ in the range from 10^{-5} to 10^5 . But the problem of choosing of the optimal value of μ is still open.

Figure 6.2: The evolution of the L-curve during the iterations for different values of μ . Colored lines correspond for the values of μ listed in the insert. The number of iterations which were done to plot the lines are pointed out in the brackets beside. Colored numbers near the lines are the number of iterations which were done to reach the data noise level $\mathcal{E}_{\text{tomo}}$ (red dashed horizontal line).

The iteration results for different μ mainly differ in the final value of the regularization term F_{reg} . A critical number for F_{reg} is the logarithm of the regularization term, $F_{\text{reg}}(\mathbf{X}_0)$, for the original field \mathbf{X}_0 . Theoretically, the value of $F_{\text{reg}}(\mathbf{X}_0)$ must be zero. But due to the noise in the boundary data, and the error in the model space due to discretization, this value is greater than zero. Hence, $F_{\text{reg}}(\mathbf{X}_0)$ is an estimate of the discretization error and noise in the boundary magnetic field. Its value in our example is indicated by a blue dashed vertical line in Fig. 6.2. The boundary noise level is denoted through \mathcal{E}_b .

Unfortunately, for a real problem, \mathbf{X}_0 is unknown and we can only roughly estimate the discretization error in the regularization term by applying it to a potential field approximation \mathbf{X}_{pot} . The black vertical line in Fig. 6.2 corresponds to the logarithm of the regularization term, $F_{\text{reg}}(\mathbf{X}_{\text{pot}})$, for the potential field approximation \mathbf{X}_{pot} which lacks the current perturbation. Here $\ln F_{\text{reg}}(\mathbf{X}_{\text{pot}}) < \ln F_{\text{reg}}(\mathbf{X}_0)$, because the relatively large field in the perturbed area causes a larger discretization error (the value of the error depends on the field-strength gradient).

Another way to estimate the lower value of the F_{reg} is the following. The elements of the matrix $\mathbf{G} \cdot \mathbf{X}_0$ (see eq. (6.5)) are the net flux through corresponding cells. The same elements of the matrix \mathbf{B} for which the corresponding cells are not cut by the boundaries are strictly zero. The elements for which the corresponding cells are cut by the boundaries are calculated from the observed on the boundaries magnetic field. They usually are not zero and under influence of noise.

It is possible to divide the regularization term into two parts: the first is calculated by involving only the cells which are not cut by the spherical boundaries, $F_{\text{reg}}^{(n)}$, and the

Figure 6.3: The regularization term calculated separately for the cells which are cut (solid lines) and not cut (long dashed lines) by the spherical boundaries. The short dashed lines represent F_{reg} calculated for the uncut cells, but without considering the cells in the perturbed area.

second involves only the cells which are cut by these boundaries, $F_{\text{reg}}^{(b)}$ (the symbols "n" and "b" are just notations here, not an exponents). The discretization error is mainly introduced by the $F_{\text{reg}}^{(n)}$ because the number of cells involved in the calculation of $F_{\text{reg}}^{(n)}$ is much higher than for $F_{\text{reg}}^{(b)}$. In the case of using a high-order interpolation in the calculation of the regularization term the discretization error can be neglected, and even for the rough linear interpolation used here this error is not significant. Although $F_{\text{reg}}^{(n)}$ can be compatible with $F_{\text{reg}}^{(b)}$ due to the much larger amount of cells involved in the calculation of the $F_{\text{reg}}^{(n)}$, the error contribution from the noisy boundary data is higher in the presented example. Fig. 6.3 shows the values of F_{reg} calculated separately for these two kinds of cells during the iterations for several values of μ . Here we see that after 47 iterations $F_{\text{reg}}^{(b)} = \mathcal{E}_b$ when $\mu \approx 5 \cdot 10^{-3}$. Even if we take $\mu = 10^{-3}$, it would not be a big fit to the noise in the boundary data. The choice of the value of μ depends on which regions must be reconstructed better than others.

It should be noted that the regularization term represented by the condition $\nabla \cdot \mathbf{B} = 0$ has a large null-space. Therefore, a field for which $F_{\text{reg}} = 0$ is not obligatory smooth. The regularization term F_{reg} differs here from conventionally chosen regularization operators (Section (2.4)), which are often proper smoothing operators. Let us introduce a

Figure 6.4: The L-curve for the reconstruction based on the Zeeman-effect data with 5 % noise level. The numbers connected with the points indicate values of μ_{reg} .

smoothness operator as

$$\begin{aligned}
 F_{\text{sm}} = \sum_{i,j,k} \left[& (B_{i,j,k}^x - B_{i+1,j,k}^x)^2 + (B_{i,j,k}^x - B_{i,j+1,k}^x)^2 + (B_{i,j,k}^x - B_{i,j,k+1}^x)^2 + \right. \\
 & + (B_{i,j,k}^y - B_{i+1,j,k}^y)^2 + (B_{i,j,k}^y - B_{i,j+1,k}^y)^2 + (B_{i,j,k}^y - B_{i,j,k+1}^y)^2 + \\
 & \left. + (B_{i,j,k}^z - B_{i+1,j,k}^z)^2 + (B_{i,j,k}^z - B_{i,j+1,k}^z)^2 + (B_{i,j,k}^z - B_{i,j,k+1}^z)^2 \right], \quad (6.8)
 \end{aligned}$$

where $B_{i,j,k}^x$, $B_{i,j,k}^y$, $B_{i,j,k}^z$ are the x -, y - and z -components of the magnetic field vector at the cell with indexes i , j , k which are counted along the x -, y - and z -axes, respectively. The smoothness term was not involved in the inversion procedure, but it is useful to plot the behavior of the logarithm of the data's error versus the logarithm of the smoothness term, F_{sm} , during the iterations for the different values of μ (Fig. 6.5). Fig. 6.5 shows that as the iteration proceeds and F_{tomog} decreases the magnetic field model involves more and more structures and F_{sm} increases. The blue dashed vertical line there corresponds to the value of the smoothness term for the original field $F_{\text{sm}}(\mathbf{X}_0)$ and can serve as a reference of values for F_{sm} we should achieve with our solution. However, we also do not want to smooth solutions for which F_{sm} is less than $F_{\text{sm}}(\mathbf{X}_0)$, because we would lose real features in the reconstruction. Fig. 6.5 shows that the values of μ laying between $10^{-3} < \mu < 5 \cdot 10^{-3}$ satisfy these criteria. For $\mu < 10^{-3}$ we obtain results which show more structures (larger F_{sm}) but also include more noise. The reconstruction for $\mu = 10^{-3}$ after 47 iterations is shown in Fig. A.4. We see that it is a better reconstruction than for the potential field approximation, at least it is possible to see the perturbed region.

Similar to the analysis described above, we have performed an analysis with F_{tomog} replaced by F'_{tomog} which includes the data error only for those rays that pass through the region magnetically influenced by the current perturbation (perturbed region). In the

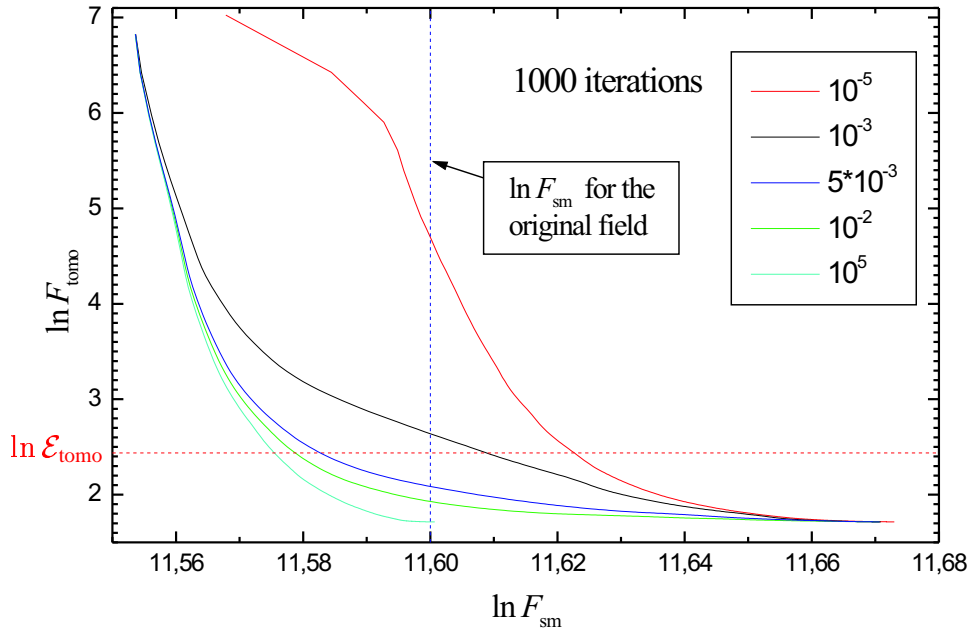

Figure 6.5: The behavior of the data's error versus the smoothness during the iterations for the different values of μ . Colored lines correspond to the values of μ listed in the insert.

Figure 6.6: The evolution of the L-curve for the perturbed region during the iterations for different values of μ . The colored lines correspond to the values of μ listed in the insert. The colored numbers near the lines are the number of iterations which were done to reach the data noise level $\mathcal{E}'_{\text{tomo}}$.

following analyses, we restrict the analyzing part of the perturbed region by the planes $z = \pm R_{\odot}/2$, $y/x = \tan(\pm \frac{\pi}{18})$ and by the conditions $x > 0$, $R_{\odot}^2 < x^2 + y^2 + z^2 < (2R_{\odot})^2$.

The Fig. 6.6 shows the behavior of the logarithm of the F'_{tomo} versus the logarithm of the regularization term, F_{reg} , calculated for all the cells, during the iterations for the different values of μ . Analogously with the Fig. 6.2, we introduce the data noise level $\mathcal{E}'_{\text{tomo}}$ for the rays passing through the perturbed region. Because the noise depends on the magnitude of the data, the value of $\mathcal{E}'_{\text{tomo}}$ is not simply proportional to the number of rays that passed through the chosen region. The value of the $\mathcal{E}'_{\text{tomo}}$ is marked by a red dashed horizontal line in the Fig. 6.6. The boundary data noise level, \mathcal{E}_b , is not so critical here because now we are interested mainly in the perturbed region. To reach the noise level $\mathcal{E}'_{\text{tomo}}$, it is necessary to perform 105 iterations when $\mu = 10^{-3}$. Figure A.5 shows the reconstruction for $\mu = 10^{-3}$ after 99 iterations.

6.6 Reconstruction based on the Hanle-effect data

For the reconstruction based on the Hanle-effect measurements of the Stokes- I , $-Q$ and $-U$ components we minimize the function

$$F = F_{\text{reg}} + \mu_I F_{\text{tomo}I} + \mu_Q F_{\text{tomo}Q} + \mu_U F_{\text{tomo}U} = |\mathbf{G} \cdot \mathbf{X} - \mathbf{B}|^2 + \sum_i [\mu_I (I_i^s(\mathbf{X}) - I_i^d)^2 + \mu_Q (Q_i^s(\mathbf{X}) - Q_i^d)^2 + \mu_U (U_i^s(\mathbf{X}) - U_i^d)^2]. \quad (6.9)$$

Here, the matrix \mathbf{G} and column-matrices \mathbf{X} and \mathbf{B} are the same as in (6.5), I_i^d , Q_i^d and U_i^d are the data of the i -th ray for the Stokes- I , $-Q$ and $-U$ components, respectively, and I_i^s , Q_i^s and U_i^s are the simulated Stokes- I , $-Q$ and $-U$ components, respectively, for the i -th ray, i.e.,

$$I_i^s = \int_{i\text{-th LOS}} \varepsilon_I dl, \quad Q_i^s = \int_{i\text{-th LOS}} \varepsilon_Q dl, \quad U_i^s = \int_{i\text{-th LOS}} \varepsilon_U dl, \quad (6.10)$$

where ε_I , ε_Q and ε_U are the magnetic-field-dependent Stokes- I , $-Q$ and $-U$ emission coefficients, respectively, that were calculated by (5.71) for the 10747 Å line or by (5.86) for the 5303 Å line.

Using the model field (Section 6.4) the test data were again calculated by a simple forward step. Then random noise was added to the tomography data and to the surface magnetic field data at the photosphere (inner boundary condition) by multiplying the test data and boundary conditions with $(1 + \delta)$, where δ is a uniformly distributed random number in the range $(-\varepsilon_n; +\varepsilon_n)$. The simulations were made, like for the Zeeman-effect case, with a noise level $\varepsilon_n = 0.05$, i.e. 5 %.

To minimize the function (6.9), the conjugate gradient method was used again. Only the Stokes- Q and $-U$ signals were used in the minimization procedure (i.e. $\mu_I = 0$), and we set $\mu_Q = \mu_U = \mu$ as their (Stokes- Q and $-U$) dimensions are the same. Again, like for the Zeeman-effect case, the potential field approximation was used as initial field configuration for the iterations.

Similar to the Zeeman-effect reconstruction procedure, to increase contribution of signals from distant rays the data of pixel $(x_p; y_p)$ was weighted with a function

$$w_{sc}(r_p) = \frac{r_p^2}{n_e(r_p)}, \quad (6.11)$$

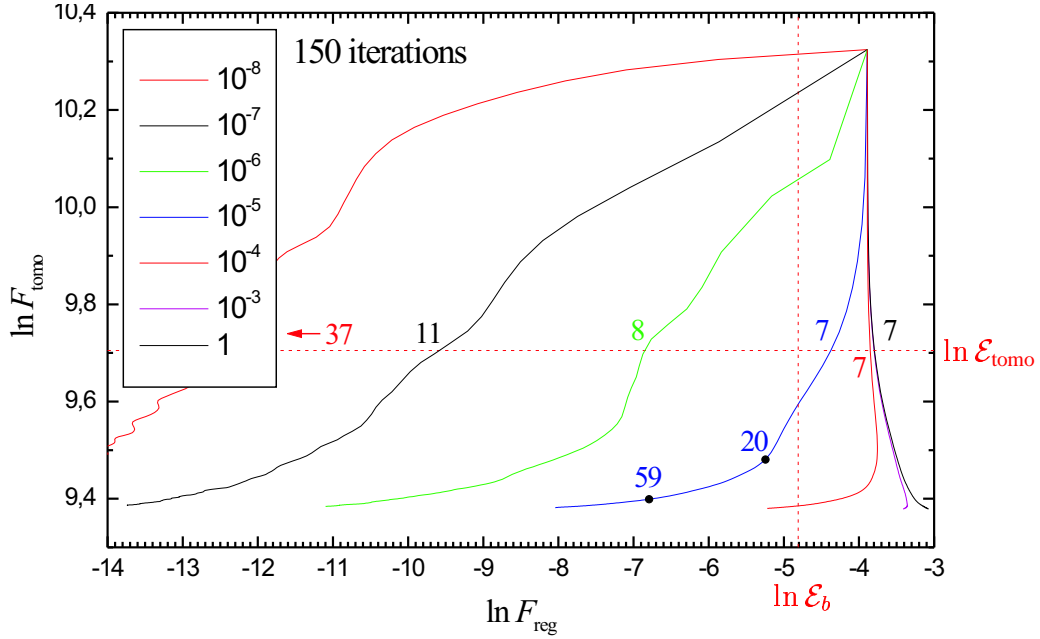

Figure 6.7: The evolution of the logarithm of the data error F_{tomo} versus the logarithm of the regularization term F_{reg} during the iterations for different values of μ and for the reconstruction based on the Hanle-effect data. The colored curves correspond to the values of μ listed in the insert. The colored numbers near the lines are the number of iterations which were needed to reach the data noise level $\mathcal{E}_{\text{tomo}}$ (red dashed horizontal line). \mathcal{E}_b is the boundary noise level in the regularization term.

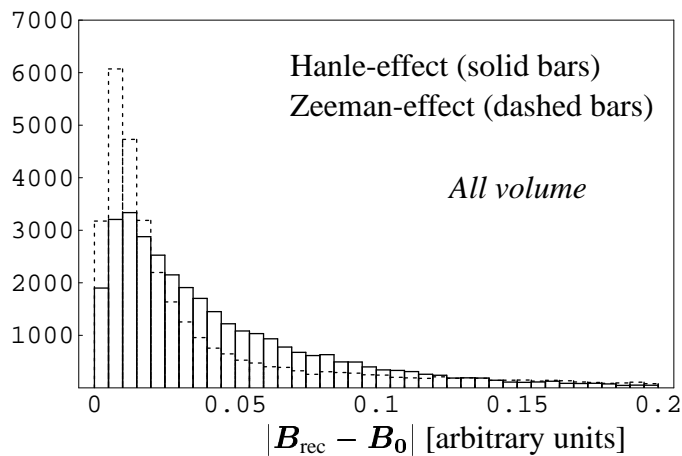

Figure 6.8: The histograms of the distribution of the difference vector magnitudes over the whole volume for the reconstructions H1 (Hanle-effect data, $\mu = 10^{-5}$, 7 iterations, solid bars) and Z1 (Zeeman-effect data, $\mu = 10^{-3}$, 47 iterations, dashed bars)

where $r_p = \sqrt{x_p^2 + y_p^2}$, and n_e is electron density.

The Fig. 6.7 shows the behavior of the logarithm of the data error, F_{tomo} , versus the logarithm of the regularization term, F_{reg} , during the iterations for different values of μ . The horizontal dashed line is the data noise level $\mathcal{E}_{\text{tomo}}$ calculated analogously to the case of the Zeeman-effect (eq.(6.7)), and \mathcal{E}_b marks the boundary data noise level in the regularization term. In order to obtain a tomography's data error $F_{\text{tomo}} \sim \mathcal{E}_{\text{tomo}}$ and a regularization error $F_{\text{reg}} \sim \mathcal{E}_b$, like for the case of Zeeman-effect data, we chose $\mu = 10^{-5}$ and stopped after 7 iterations (see Figs. A.6a,b,c for an overview of cross sections of the reconstructed field). To quantify the reconstruction error we calculated for every cell the magnitude of the difference vector between the reconstructed and the original model magnetic field vectors. For an ideal solution, these vectors must approach zero as close as possible. The histograms of the distribution of the magnitudes of the difference vectors for the three reconstruction methods are shown in Fig. 6.8. The distribution has a peak at the value of $|\mathbf{B}_{\text{rec}} - \mathbf{B}_0|$ equal to ~ 0.015 . Only in a very few cases exceeds the distance 0.2, while the magnitudes of model field vectors, $|\mathbf{B}_0|$, are distributed in the region $1 < |\mathbf{B}_0| < 13.4$, with a maximum at ~ 1.5 and average value of ≈ 3.3 . So, the reconstruction error is relatively small.

To find the iteration number when we will have a better reconstruction for the perturbed area alone, we calculate the data noise level $\mathcal{E}'_{\text{tomo}}$ only for the rays passing through the perturbed region like in the previous section. The data error F'_{tomo} calculated only for these rays reaches the level $\ln \mathcal{E}'_{\text{tomo}}$ after ~ 59 iterations. Trying to keep the regularization term error the same like for the case of the Zeeman-effect data (i.e., near \mathcal{E}_b), we have to stop the minimization procedure after 20-th iteration (see Figs. A.7a,b,c for an overview of cross sections of the reconstructed field).

6.7 Comparison of the Hanle- and Zeeman-effect solutions

Here, we will compare the solutions H2 based on the Hanle-effect data (with $\mu = 10^{-5}$ and stopped after 20 iterations, Fig. A.7) and Z2 described in Section 6.5 (Zeeman-effect data, $\mu = 10^{-3}$, 99 iterations). The histograms of the distribution of the magnitudes of the difference vectors in the perturbed region for these solutions are shown in the Fig. 6.9. The distributions have their maxima at values of $|\mathbf{B}_{\text{rec}} - \mathbf{B}_0|$ equal to ~ 0.1 for the Hanle-effect reconstruction and ~ 0.3 for the Zeeman-effect reconstruction, and in only a few cases this value is near or greater 4, while the magnitudes of the model field vector, $|\mathbf{B}_0|$, in the perturbed region are distributed in the interval $1 < |\mathbf{B}_0| < 13.4$, with maximum at ~ 1.6 and average value of ≈ 3.9 . Although, the bar near zero is for the Hanle-effect solution higher than for the Zeeman-effect solution, but the bars being more far from zero and ranging between the values $1 < |\mathbf{B}_{\text{rec}} - \mathbf{B}_0| \lesssim 2$ are higher than for the Zeeman-effect solution. Therefore, it is difficult to say which solution is better.

The Zeeman effect is insensitive to the irrotational part of the vector field, and in the present observing geometry when observation directions are all perpendicular to the rotation axis is insensitive to the z -component of the field vectors. Therefore, one would expect that a reconstruction based on Zeeman effect data gives worse result for these field components. The histograms in the Fig. 6.10 illustrate this situation. The his-

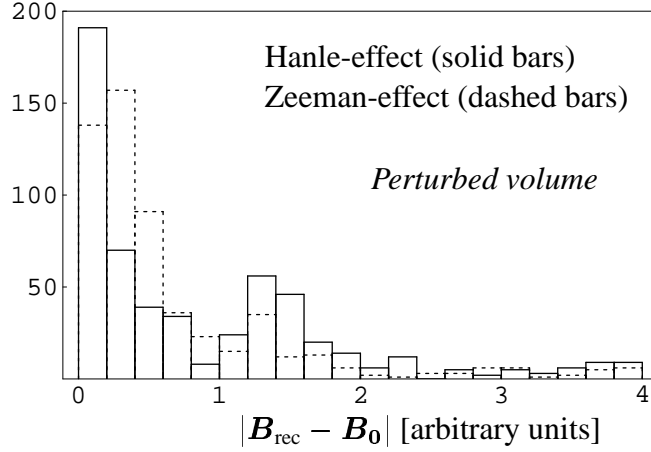

Figure 6.9: The histograms of the distribution of the difference vector magnitudes over the perturbed volume for the reconstructions H2 (Hanle-effect data, $\mu = 10^{-5}$, 20 iterations, solid bars) and Z2 (Zeeman-effect data, $\mu = 10^{-3}$, 99 iterations, dashed bars).

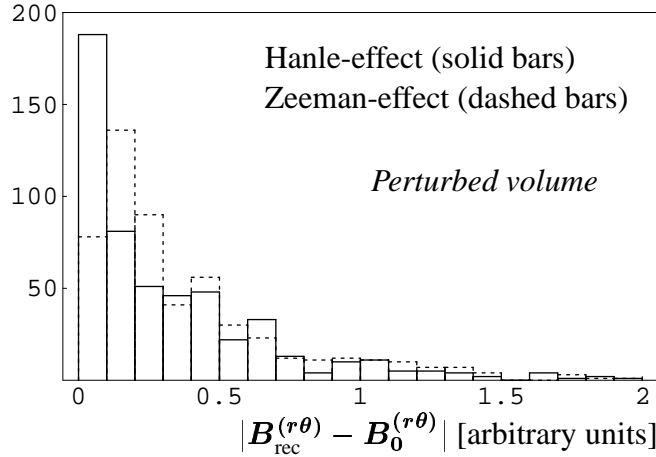

Figure 6.10: The histograms of the distribution of the errors of the meridional-plane component of the field vectors over the perturbed volume for the reconstructions H2 (Hanle-effect data, $\mu = 10^{-5}$, 20 iterations, solid bars) and Z2 (Zeeman-effect data, $\mu = 10^{-3}$, 99 iterations, dashed bars).

tograms shows the distributions of the errors of the reconstructed field vector components, $|\mathbf{B}_{\text{rec}}^{(r\theta)} - \mathbf{B}_0^{(r\theta)}|$, laying in the meridional planes defined by the rotation axis and point where field vector is looking for. Here, $\mathbf{B}^{(r\theta)} = B^{(r)}\hat{\mathbf{e}}_r + B^{(\theta)}\hat{\mathbf{e}}_\theta$, where $B^{(r)}$ and $B^{(\theta)}$ are the radial and meridional components of the magnetic field vector, respectively. The $\hat{\mathbf{e}}_r$ and $\hat{\mathbf{e}}_\theta$ are the unit vectors defining the spherical coordinate system centered at the given point in the corona, $\hat{\mathbf{e}}_r$ is co-directed with the radius vector, $\hat{\mathbf{e}}_\theta \perp \hat{\mathbf{e}}_r$, the vectors $\hat{\mathbf{e}}_r$, $\hat{\mathbf{e}}_\theta$ and \mathbf{Oz} lie in the same plane, and $\hat{\mathbf{e}}_\theta \cdot \mathbf{Oz} \geq 0$.

The Fig. 6.11a shows the histogram of the distribution of the errors of the azimuthal component $B^{(\phi)}$ of the reconstructed field vectors. We see that for this component the reconstruction based on the Zeeman-effect data gives better result than the one based on the Hanle-effect data. This is again understandable because, with the present viewing

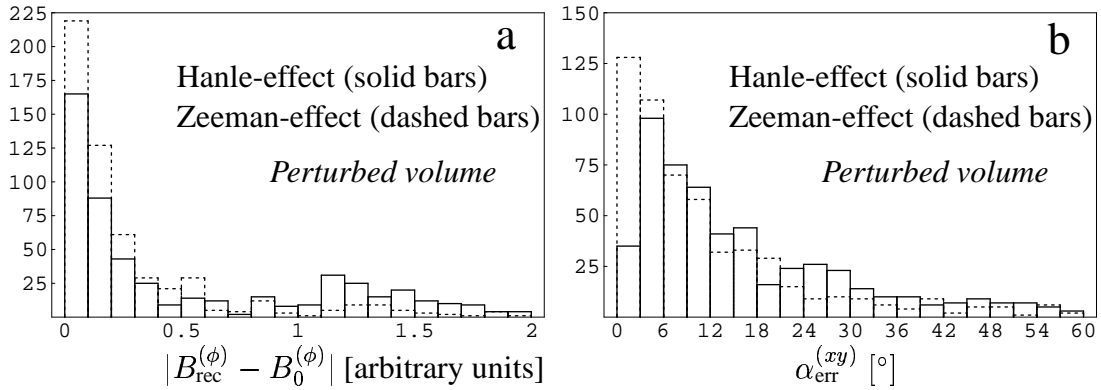

Figure 6.11: The histograms of the distributions of the errors of the azimuthal components $B^{(\phi)}$ of the field vectors (a) and the angle between the x - y -plane vector components of the reconstructed and model fields (b) over the perturbed volume for the reconstructions H2 (Hanle-effect data, $\mu = 10^{-5}$, 20 iterations, solid bars) and Z2 (Zeeman-effect data, $\mu = 10^{-3}$, 99 iterations, dashed bars)

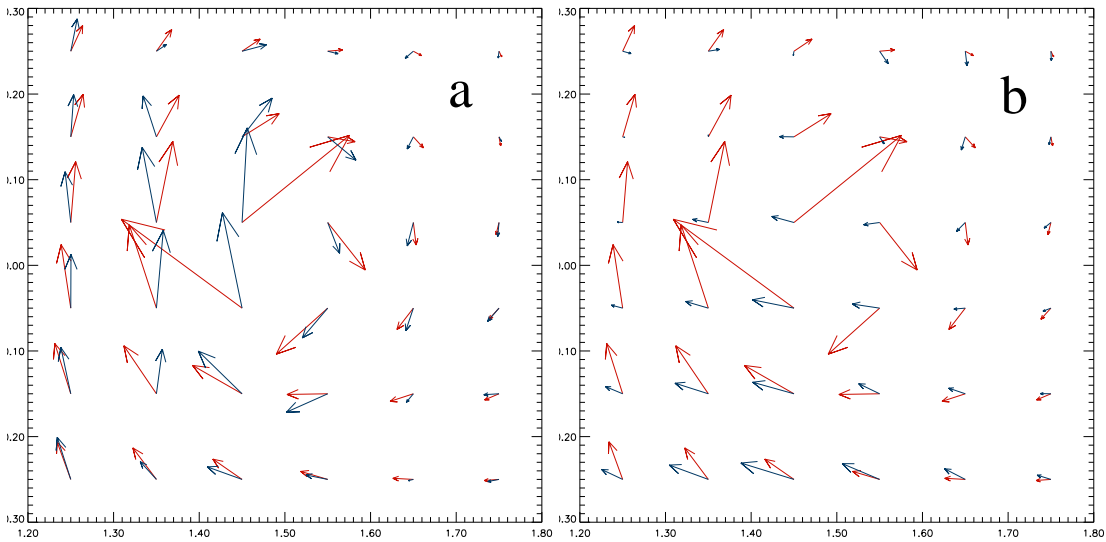

Figure 6.12: The cross-sections at the $z = 0.15R_{\odot}$ of the model field (red vectors) and reconstructed field (blue vectors). The reconstructions are Z2 based on the Zeeman-effect data (a) and H2 based on the Hanle-effect data (b)

geometry, the problem of definition of the azimuthal field component is more ill-posed for the Hanle effect than for the Zeeman effect. Let us explain this in more detail. Only the x - and y -components of the field vector contribute to the $B^{(\phi)}$, and the x - y -plane components of the field vectors give no contribution to the Stokes- U signal. For the x - y -plane components we only have information about the angle θ_{xy} between LOS and this vector component through the function $\sin^2 \theta_{xy}$ which introduces ambiguities, i.e. we have 4 possible directions of the field vector, and therefore the Hanle effect cannot distinguish a field vector directed along the LOS from one directed against the LOS, while the Zeeman effect does (due to the $\cos \theta_{xy}$ dependence). Moreover, the Hanle effect

does not provide any information about the strength of the magnetic field.

Is it possible that the big error in the $B^{(\phi)}$ component in the perturbed region is due to the big error in the absolute value of the x - y -plane vector component but not due to its direction in these planes? Fig. 6.11b shows histogram of distribution of the angles between the x - y -plane vector component of the reconstructed and model fields. We see that this is not the case.

Finally, the Fig. 6.12 qualitatively shows the difference between the reconstructions and the original model field in the plane $z = 0.15R_{\odot}$ and around the perturbed region.

6.8 Reconstruction based on the Hanle-effect: Zeeman-effect solution as initial field

Even though the Zeeman-effect data give a better reconstruction for the particular field configuration than the Hanle-effect data, we want to explore in this section whether the reconstruction based on the Zeeman-effect data can be improved if they are supplemented by the Hanle-effect observations. For this purpose, we repeat the inversion calculations for the Hanle-effect data as in Section 6.6, but this time we use the Zeeman-effect solution Z1 (the solution with $\mu = 10^{-3}$ obtained after 47 iterations) as initial field configuration in the iterations. All others parameters used in the iterations are the same as in section

Figure 6.13: The evolution of the logarithm of the data error F_{tomo} versus the logarithm of the regularization term F_{reg} during the iterations for different values of μ and for the reconstruction based on the Hanle-effect data. The Zeeman-effect solution Z1 was used as initial field in the iterations. The colored curves correspond to the values of μ listed in the insert. The colored numbers near the lines are the number of iterations which were needed to reach the data noise level $\mathcal{E}_{\text{tomo}}$ (red dashed horizontal line). \mathcal{E}_b is the boundary noise level in the regularization term.

6.6.

The Fig. 6.13 shows the behavior of the logarithm of the data error, F_{tomo} , versus the logarithm of the regularization term, F_{reg} , during the iterations for different values of μ . The horizontal dashed line is the data noise level $\mathcal{E}_{\text{tomo}}$ calculated analogously to the case of the Zeeman-effect (equation (6.7)), and \mathcal{E}_b marks the boundary data noise level in the regularization term. In order to obtain a tomography's data error $F_{\text{tomo}} \sim \mathcal{E}_{\text{tomo}}$ and a regularization error $F_{\text{reg}} \sim \mathcal{E}_b$, like for the case of Zeeman-effect data, we had to use $\mu = 10^{-5}$ and to stop after 5 iterations (ZH1).

The comparison of this solution with the related reconstruction Z1 based on the Zeeman-effect data (obtained after 47 iterations with $\mu = 10^{-3}$ and depicted in the Figs. A.4a,b,c) is presented by the histogram in the Fig. 6.14a, and comparison with the related reconstruction H1 based on the Hanle-effect data when the potential field approximation was used as initial field (after 7 iterations, figures A.6a,b,c) is presented by the histogram in the Fig. 6.14b. From the plots in the Fig. 6.14 it is difficult to say which of the two Hanle-effect reconstructions is better: the one where Zeeman-effect solution was used as initial condition or the other with potential field approximation as initial field. But, these Hanle solutions represent mainly the main dipole field. For its reconstruction is sufficient to apply the potential field approximation method.

As we are interested in the reconstruction of the non-potential part of the magnetic field, we restrict here our comparison to the perturbed area. To find the iteration number when we have the better reconstruction for the perturbed area, we again like in previous sections calculate the data noise level $\mathcal{E}'_{\text{tomo}}$ only for the rays passing through the perturbed region. The data error F'_{tomo} calculated only for these rays reaches the level $\ln \mathcal{E}'_{\text{tomo}}$ after ~ 30 iterations (ZH3). Trying to keep the regularization term error the same like for the case of the Zeeman-effect data (i.e., near \mathcal{E}_b), we have to stop the minimization procedure after 13-th iteration (ZH2-solution). The cross sections of \mathbf{B} for this reconstruction are shown in the Fig. A.9a,b,c.

The histogram of the distribution of the magnitudes of the difference vectors ($\mathbf{B}_{\text{rec}} -$

Figure 6.14: The histograms of the distribution of the difference vector magnitudes over the all volume: (a) - for the reconstructions H1 (Hanle-effect data, $\mu = 10^{-5}$, 5 iterations, solid bars) and Z1 (Zeeman-effect data, $\mu = 10^{-3}$, 47 iterations, dashed bars); (b) - for the reconstructions both based on the Hanle-effect data, but one is ZH1 (solid bars) and other is H1 (dashed bars). For comparison, the minimal value of the magnitude of the model field \mathbf{B}_0 is ~ 1 .

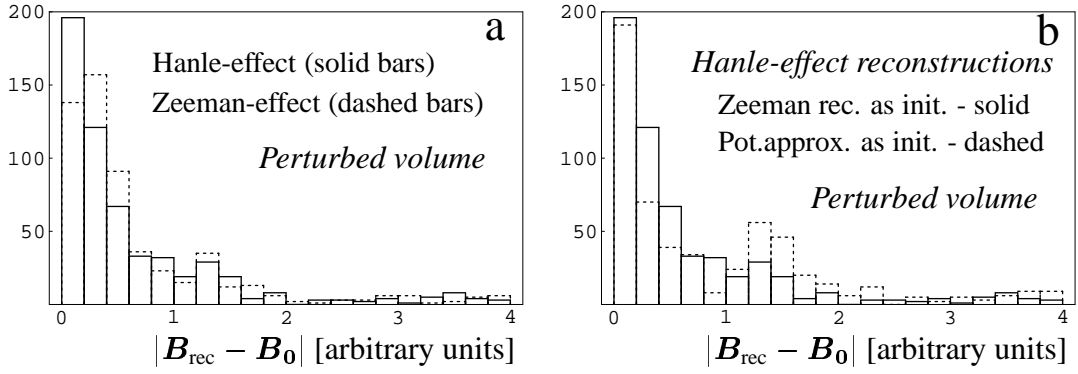

Figure 6.15: The histograms of the distribution of the difference vector magnitudes over the perturbed volume. The solid bars on the both panels represent the Hanle-effect solution ZH2 for which the Z1 solution (dashed bars on the panel (a)) was used as initial field. The dashed bars on the panel (b) represent the Hanle-effect solution H2 whereby the potential field approximation was used as initial condition. For comparison, the average value of the magnitudes of the model field vectors \mathbf{B}_0 in the perturbed region is ≈ 3.9 .

Figure 6.16: The cross sections in the $z = 0.15R_\odot$ plane of the model field (red vectors), reconstruction based on the Zeeman-effect (green vectors, Z2-solution), and reconstruction based on the Hanle-effect (black vectors, ZH2-solution).

\mathbf{B}_0) in the perturbed region for this solution is shown in the Fig. 6.15. There are also shown the related histograms for the Zeeman-effect reconstruction Z2 giving the better reconstruction of the perturbed area (with $\mu = 10^{-3}$ and stopped after 99 iterations, panel *a*) and, in the panel *b*, for the Hanle-effect reconstruction H2 whereby the potential field approximation was used as initial conditions ($\mu = 10^{-5}$, after 20 iterations, Sections 6.6 and 6.7). We see that the reconstruction procedure based on the Hanle-effect data and applied after the Zeeman-effect solution gives a better approximation to the model field than when the potential field approximation was used as initial field configuration in the iterations.

7 Conclusion

The goal of the thesis was to investigate the possibility to use the observations of the longitudinal Zeeman effect and/or Hanle effect in coronal emission lines for a reconstruction of the coronal magnetic field. The tomographic inversion problem which we had to solve is considerably more difficult than the traditional scalar tomography inversion problems.

For example, from longitudinal Zeeman-effect data alone, even if we assume the simplifying magnetograph formula to hold, we can only determine the solenoidal part of a vector field \mathbf{V} , which is a product of the magnetic field with a density and temperature dependent weight function. The knowledge of the sources of \mathbf{V} , or likewise the fact that $\nabla \cdot \mathbf{B} = 0$, does not completely cure the problem since a potential field contribution to \mathbf{V} still remains undetermined. The incorporation of $\nabla \cdot \mathbf{B} = 0$ in our inversion procedure as a regularization constraint, however, remedies these two deficits of the Zeeman effect data: $\nabla \cdot \mathbf{B}$ is forced to become zero inside our computational domain (at least within the numerical precision of our code) and the calculation of $\nabla \cdot \mathbf{B}$ at the domain boundary allows to integrate photospheric magnetic field observations into the inversion in a natural way. Since this photospheric field enforces a boundary condition on our magnetic field solution, the unknown potential field contribution of the solution is uniquely specified.

The theoretical predictions whether an inversion of the Hanle-effect data would be possible are less obvious. The Hanle-effect data of coronal long-lived line transitions (resonance scattering) which we considered in this thesis give no information about the magnitude of the field nor its unique direction. It only yields a weighted line-of-sight integral of the orientation of the magnetic field. Obviously, it is the photospheric magnetic field data included in our inversion code which decides about the magnitude and the sign of the solution magnetic field.

From these considerations it is clear that a data set for the reconstruction of the coronal field from coronal Hanle and longitudinal Zeeman effect data must be supplemented by photospheric normal magnetic field observations to possibly give a unique reconstruction. We note that the reconstruction of the coronal field from the photospheric data alone requires to solve an extrapolation problem, which has its own difficulties and limits as we briefly mentioned in the introduction. Hence a complete data set needed to achieve a reconstruction of the coronal magnetic field with our method comprises:

- Spectropolarimetric Zeeman and/or polarimetric Hanle effect measurements above the Sun's limb for half a solar rotation, i.e., for about 14 days.
- A solar surface magnetogram of the vertical photospheric magnetic field component for the entire surface of the Sun.

While solar surface magnetograms today are standard observational results and are readily

available, the coronal Hanle effect and especially the coronal Zeeman effect observations are still rare. The experimental effort is considerable and the Zeeman-effect observations have only been successfully performed recently. Ideally, Hanle- and Zeeman-effect observations are made for the same line by a spectropolarimetric measurement of all four Stokes components as in Lin et al.(2004) (see also Fig. 1.1).

The time cadence and the spatial resolution of the observations have great influence on the spatial resolution of the reconstructed magnetic field solution. A precise relationship is difficult to give but could be determined empirically with test calculations similar to those presented here. We also have not addressed the problem of how a non-stationary coronal magnetic field contaminates our solution which is obtained under the strict assumption of stationarity.

In this thesis we demonstrated by means of test calculations that an inversion of the coronal Hanle- and longitudinal Zeeman-effect data in the way proposed above is possible. We have developed a numerical tomography inversion code to perform the test calculations. The code has been written in Fortran and parallelized with OpenMP (shared memory parallelization). The code so far has been used with artificial data only but it is ready for use of real data. Improvements with respect to computation time and memory requirements need to be made for an efficient use. Also the numerical algorithm may be accelerated if a more effective preconditioning scheme is implemented with the conjugate gradient method employed for the minimization procedure. Most of the test calculations presented in this thesis were performed for a corona discretized on a rectangular grid of $40 \times 40 \times 40$ cells, the artificial observations were represented by 36 images from equally spaced viewing angles and with a spatial pixel resolution matched to the resolution of the coronal grid. An inversion of this resolution requires ~ 260 Mbytes of storage and a computation time (on a single 1.28 GHz UltraSPARC-IIIi processor) of about 1.5 s per iteration step if the Zeeman effect data is used. For Hanle-effect data the computation time increases to 6 minutes per iteration, because the inversion problem in this case becomes nonlinear.

Using this inversion code, we have in this thesis only investigated a single model field configuration. This model comprised a background solar dipole field with a north-south orientated coronal current embedded. While the potential field component (essentially the dipole field) can be reproduced from the photospheric surface observations alone by use of Green's theorem, the field perturbations due to the current loop are practically impossible to be reconstructed by extrapolation methods. The main test of our calculations therefore was to find out the quality with which this perturbation field was reproduced. As it was emphasized in the introduction, this non-potential part of the coronal field is decisive for a quantitative understanding of many coronal processes which are often driven by a loss of stability of the coronal magnetic field configuration.

Good agreement between the model field and our field reconstruction were obtained when we used artificial Zeeman effect data as input. Hanle effect data gave less satisfactory results. We presume that the reason is the north-south geometry of the current loop. The perturbation magnetic field of this current produces a much stronger response in the longitudinal Zeeman than in the Hanle effect observations. This should be different for current loops with east-west orientation which should better be visible in the Hanle-effect data. These latter loops should occur more often at lower height ($\lesssim 0.2R_{\odot}$) as active bipolar regions are mostly orientated in east-west direction and the dominant

current should flow along the magnetic field lines. Older bipolar regions however are tilted into the meridional direction by the differential rotation of the Sun's surface. As an example of a near-meridional loop, Fig. 7.1(a) shows an EIT image of a magnetic flux closure across the equator between two active regions. The field which was used as a test field (Fig. 7.1b,c) shows very similar deformations near the current loop. Note, however, that our test field model is not force free. Also, at higher latitudes and higher altitudes above the surface, coronagraph observations suggest that streamer-type loop systems are common which are also close to the test field model. The test simulations have shown that:

- The tomographic inversion based on the data for the Hanle effect and(or) longitudinal Zeeman effect, and on the constraint $\nabla \cdot \mathbf{B} = 0$, allows one to reconstruct the non-potential component of the magnetic field, while a traditional potential field approximation reconstructs only the potential field component.
- The tomographic inversions based on the Hanle effect and longitudinal Zeeman effect, have different precision for the different vector components of the field, depending on the configuration of the reconstructing field. Particularly, for the case of observation of a vortex-like field situated in the plane perpendicular to the rotation axis, the vortex is hardly seen in the reconstruction based on the Hanle effect, while the reconstruction based on the Zeeman effect gives satisfactory result for this field. The inversion based on the Hanle effect gives more precise result for the meridional component of the magnetic field than an inversion based on the Zeeman effect.

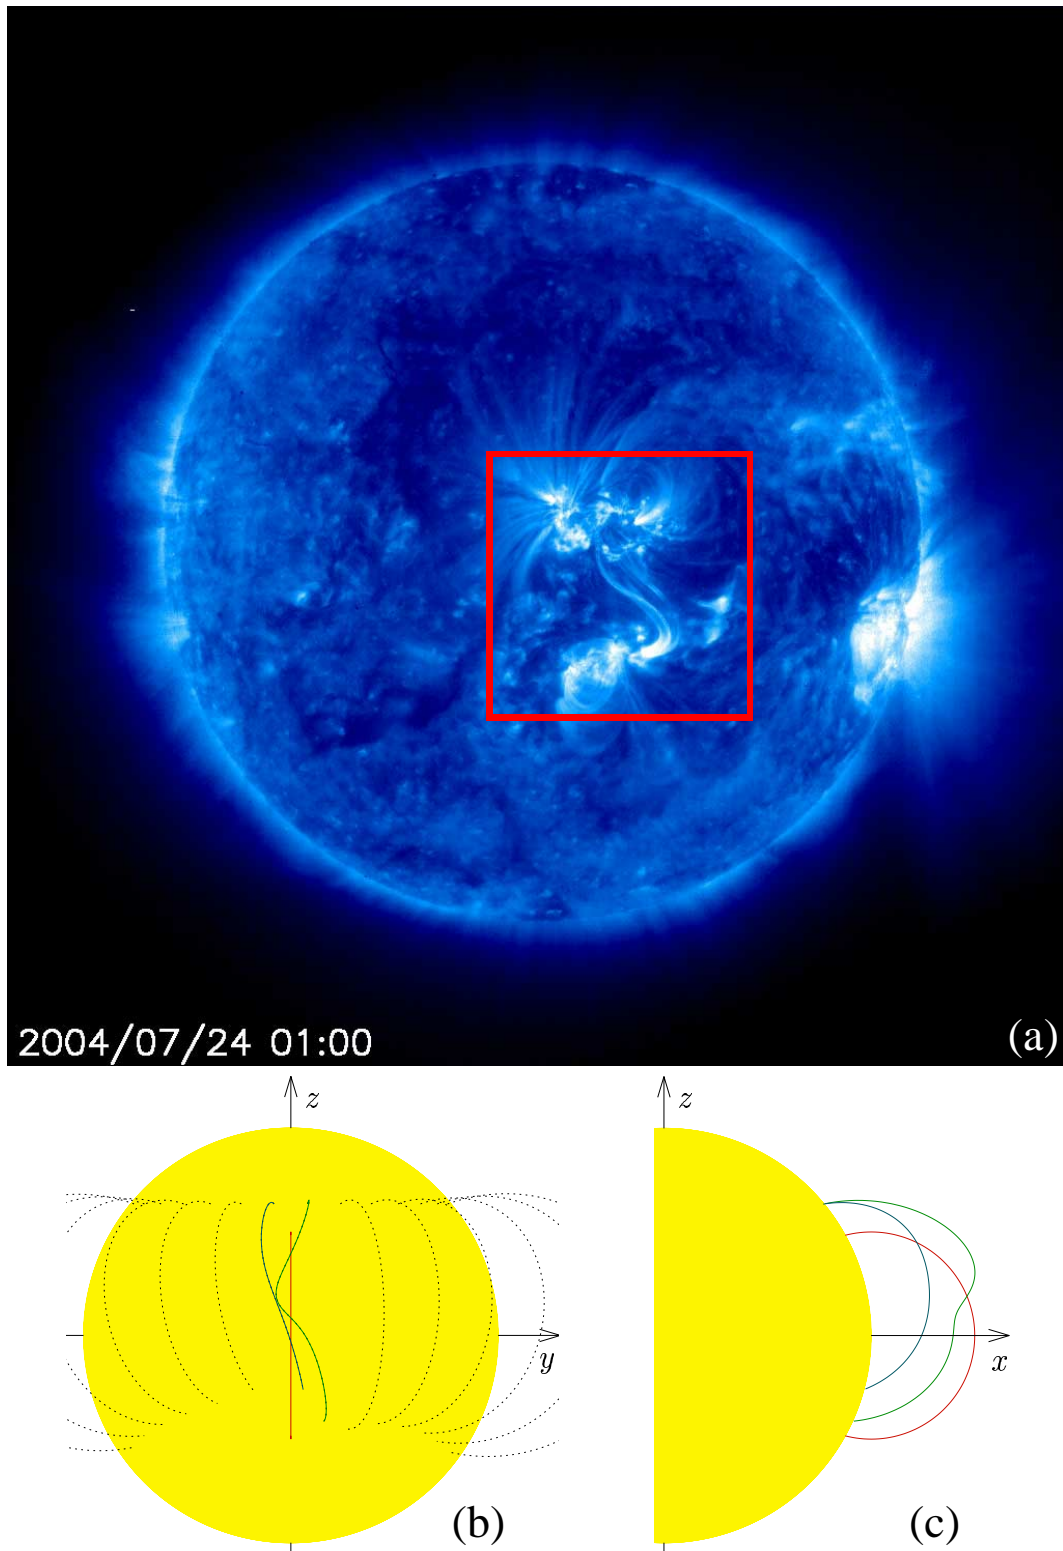

Figure 7.1: An EUV image made by the EIT instrument on board the SOHO spacecraft (a). The image was taken at the emission line of Fe XII at $\lambda = 171 \text{ \AA}$. It shows a magnetic flux closure across the equator between two active regions (inside red box), and field lines of the test model (lower pictures). Panel (b) shows the view from the $x = +\infty$ direction, and (c) shows the view from the $y = -\infty$ direction. The most perturbed field lines are marked by blue and green colors. The perturbing current loop is shown by the red curve.

Outlook

The results produced by the code developed in this thesis demonstrated that it is in principle possible to reconstruct the coronal magnetic field from coronal Hanle-effect and/or Zeeman-effect data. The present study is to our knowledge the first investigation which uses tomographic inversion techniques for this task. However, this thesis can only be a first step and several questions remain to be answered and further improvements should be made:

- As mentioned above, different and more realistic coronal magnetic field configurations, e.g., the field above active regions or more realistic streamer-type field structures should be studied to find out which details of the field can or cannot be reconstructed and how much the Hanle effect or longitudinal Zeeman effect observations contribute to the respective solutions. It would also be interesting to find out how much is gained if both observations were available.
- A common problem when inversion codes are applied to real data is the influence of the instrument noise on the solution. With the code we have developed, we can study with test calculations systematically how much noise is tolerable to achieve a certain precision of the solution. The signal-to-noise ratio that we obtain by these means can then be used to determine the integration time for the coronal Hanle and Zeeman effect observations. Since the integration time is about an hour for typical observations of this kind, this information could be highly relevant.
- Another topic that should be investigated is the influence of data gaps on the inversion result. Since the Hanle and Zeeman effect observations are made from the ground, missing viewing directions may well occur during the 14-day observing sequence. Gaps in the data obviously reduce the quality of the inversion result but it is not obvious how sensitively the result is affected by them.
- Observations of the Faraday rotation of the linearly polarized radio signals traveling through the corona give information very similar to the longitudinal Zeeman effect. However, the data is obtained at a given time only along a single line of sight rather than on a whole set of lines of sight corresponding to the pixels of an image. It would be interesting to study how useful these sparse measurements are for the reconstruction of the coronal field. A one of the examples for coronal Faraday-rotation observations are the measurements of Jensen et al. (2005), who used the radio signal of the Cassini spacecraft during its passage behind the Sun as the radio source.

- In the code used in this thesis we neglected the alignment factor (see eq. (5.56)). As discussed in Section 5.12, a finite alignment factor will modify the numerical expressions for the inversion of the longitudinal Zeeman-effect data by about 30 % or less. For a quantitative application of our code to real data, a calculation of the alignment factor should be included.
- The inversion procedure presented here could be looked at as a first step towards a systematic line-of-sight inversion of all four Stokes components which would then yield not only the magnetic field but also the coronal density (mainly from the Stokes- I component)

For many issues on this list, the inversion code developed here can be used to find an empirical answer.

A Appendix

A.1 Potential field approximation

The potential field approximation is often used to reconstruct the magnetic field in the solar corona on the basis of measurements of the magnetic field at the photospheric level. The assumption for this model is that there are no electric currents above the photosphere, i.e.,

$$\nabla \times \mathbf{B} = 0. \quad (\text{A.1})$$

In this case the magnetic field can be written as the gradient of a scalar potential Φ ,

$$\mathbf{B} = -\nabla \Phi. \quad (\text{A.2})$$

Since $\nabla \cdot \mathbf{B} = 0$, we need to solve Laplace equation

$$\nabla^2 \Phi = 0. \quad (\text{A.3})$$

Gauss (1839) showed that having the radial component of the magnetic field, B_r , on the photosphere is a sufficient boundary condition, and the expansion of the potential Φ in spherical harmonics, Y_{lm} , gives a complete solution:

$$\Phi(r, \theta, \phi) = \sum_{l=0}^{\infty} \sum_{m=-l}^l \left(A_{lm} r^l + B_{lm} r^{-(l+1)} \right) \cdot Y_{lm}(\theta, \phi), \quad (\text{A.4})$$

with the spherical harmonics expressed through the associated Legendre polynomials, $P_l^m(\cos \theta)$, by the equation

$$Y_{lm}(\theta, \phi) = \sqrt{\frac{2l+1}{4\pi} \frac{(l-m)!}{(l+m)!}} P_l^m(\cos \theta) e^{im\phi} \quad (\text{A.5})$$

The coefficients A_{lm} and B_{lm} must be calculated from the boundary conditions. If we suppose $|\mathbf{B}|(r \rightarrow \infty) = 0$ (no magnetic field sources above the photosphere), then

$$A_{lm} = 0, \quad (\text{A.6})$$

$$B_{lm} = -\frac{C_{lm} r_0^{l+2}}{l+1}, \quad (\text{A.7})$$

where

$$C_{lm} = \int_0^{2\pi} \int_0^\pi (-1)^m Y_{l,-m}(\theta, \phi) B_r(r_0, \theta, \phi) \sin(\theta) d\theta d\phi. \quad (\text{A.8})$$

This model does not represent a real magnetic field configuration since observations show that the coronal magnetic field is dominantly radial above approximately two solar radii. To improve the situation, Schatten, Wilcox and Ness (1969) introduced a source sphere at distance r_1 from the solar surface where the magnetic field becomes radial. In this case the coefficients A_{lm} and B_{lm} for $l \geq 1$ are:

$$A_{lm} = \frac{C_{lm} r_0^{2+l}}{r_1^{1+2l} + l(r_0^{1+2l} + r_1^{1+2l})}, \quad (\text{A.9})$$

$$B_{lm} = -\frac{C_{lm} r_0^{2+l} r_1^{1+2l}}{r_1^{1+2l} + l(r_0^{1+2l} + r_1^{1+2l})}. \quad (\text{A.10})$$

For $l = 0$ the coefficient A_{00} can be chosen arbitrary and

$$B_{00} = -\frac{C_{00} r_0^2}{\sqrt{4\pi}} = 0 \quad (\text{there is no magnetic monopole allowed}). \quad (\text{A.11})$$

There are several ways to find the radial component of the magnetic field vector at the solar surface from magnetogram measurements (MDI). The magnetogram gives the LOS component of the magnetic field at the photosphere. Suppose the magnetic field is constant during solar rotation and on average radial at the photosphere. Then, by measuring the LOS component of the field, B^{LOS} , during the central meridian passage, one finds that

$$B_r = \frac{B^{\text{LOS}}}{\sin \theta}, \quad (\text{A.12})$$

where θ is the latitude ($0 < \theta < \pi$).

In the second way, it is also assumed that the magnetic field is constant during a solar rotation, but it has no radial structure. Let us consider a region at longitude ϕ with respect to the central meridian, and latitude θ (Fig. A.1). It is possible to measure B_i^{LOS} for this particular region for at several positions ϕ_i . So, we have a system of linear equations for a single region:

$$B_r \sin \theta \cos \phi_i + B_\theta \cos \theta \cos \phi_i - B_\phi \sin \phi_i = B_i^{\text{LOS}}, \quad (\text{A.13})$$

where B_θ and B_ϕ are the latitudinal and longitudinal components of the field vector \mathbf{B} , respectively. Then, if we suppose that the magnetic field is axisymmetric ($B_\phi = 0$), and measuring LOS component, B^{LOS} , during a central meridian passage ($\phi_i = 0$), the values of the B_r and B_θ can be found from (A.13) by least-square fitting (for example, by SVD-method). Here the inclination of the Sun's pole was not taken into account.

A.2 Force-free field reconstruction

The force-free magnetic field approximation is valid when the electrical currents are parallel to the magnetic field. This occurs in the low corona where the plasma β is small. A force-free magnetic field must satisfy the equations:

$$\nabla \cdot \mathbf{B} = 0, \quad (\text{A.14})$$

$$4\pi \mathbf{J} = \nabla \times \mathbf{B} = \alpha \mathbf{B}, \quad (\text{A.15})$$

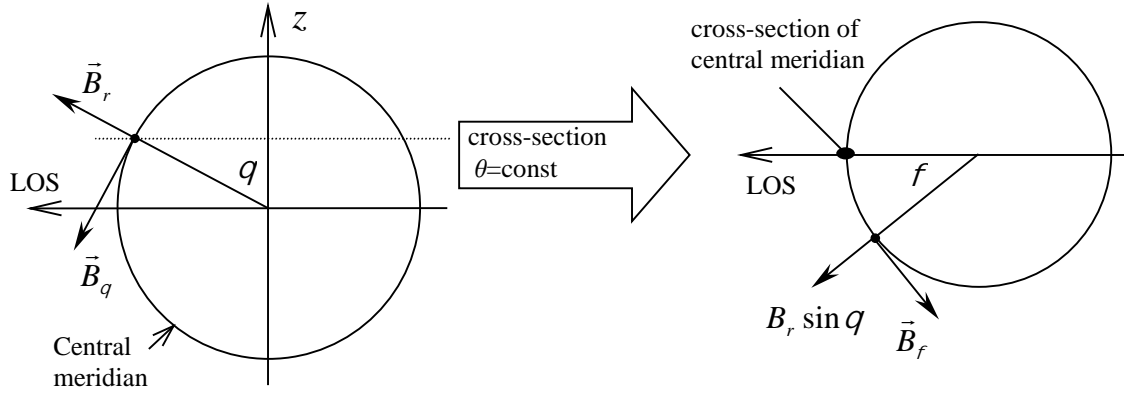

Figure A.1: Definition of field components at the photospheric level.

where \mathbf{J} is current density, and α is function of the spatial coordinates. Taking the divergence of (A.15) and using (A.14) one obtains

$$\mathbf{B} \cdot \nabla \alpha = 0, \quad (\text{A.16})$$

which shows that α is constant along individual field lines.

Solution (A.14) and (A.15) require a magnetic field at the photospheric level as boundary condition. The case of constant α , the *linear force-free* model, has been widely investigated by plenty of authors (Nakagawa et al. 1971; Nakagawa & Raadu 1972; Seehafer 1978; Alissandrakis 1981; Chiu & Hilton 1977; Semel 1988).

However, the linear force-free model is still far from representing a real magnetic field configuration. Observations show that α is not constant even within a single active region (Levine 1976; Krall et al. 1982; Schmahl et al. 1982; Gary 1987). Therefore the *nonlinear force-free* model with non-constant α is more realistic (Sakurai 1981; Cuperman et al. 1990; Wiegmann 2004; Weatland 2004).

A.3 Michelson Doppler Imager (MDI)

The Michelson Doppler Imager (MDI) on SOHO makes images of the Sun on a CCD camera with resolution of 1024×1024 pixels. The filter system of the instrument (front window, the blocker, the Lyot and two wide-field tunable Michelson interferometers) allows to make narrow-band (94 mÅ) image near the Ni I 6768 Å photospheric absorption line. Images are obtained at five fixed wavelength equally separated by 75 mÅ with intensities I_0, I_1, I_2, I_3 and I_4 . I_0 is near continuum, I_1 and I_4 is centered on the wings, and I_2 and I_3 is centered near the core of the Ni I line at the center of solar disk. The depth of the Ni I line is the continuum intensity minus the line-center one and compute from the four images:

$$I_{\text{depth}} = \sqrt{2((I_1 - I_3)^2 + (I_2 - I_4)^2)}. \quad (\text{A.17})$$

The continuum intensity near the Ni I line is

$$I_c = 2I_0 + I_{\text{depth}}/2 + (I_1 + I_2 + I_3 + I_4)/4. \quad (\text{A.18})$$

The Doppler shift (velocity) is computed from a ratio

$$\begin{aligned} & (I_1 + I_2 - I_3 - I_4)/(I_1 - I_3), \text{ if numerator } > 0, \\ & (I_1 + I_2 - I_3 - I_4)/(I_4 - I_2), \text{ if numerator } \leq 0, \end{aligned} \tag{A.19}$$

using results obtained from parameterized solar line profiles and the measured filter transmission profiles (Scherrer et al. 1995).

The difference between the Doppler shifts taken separately in right and left circularly polarized light is roughly proportional to the LOS-component of the magnetic field averaged over the resolution element. This operation is made by inserting the polarizers.

A full-disk image has a plate scale of $2''$ per pixel and a resolution of $4''$. Also, MDI produces a focused image of an $11'$ square field with higher resolution ($1.25''$) and a plate scale of $0.625''$ per pixel.

A.4 Spherical tensor \mathcal{T} for polarimetry of magnetic dipole transitions in reducible representation

$\mathcal{T}_{-1,-1}(0, \Omega)$	$= \frac{1}{4}(1 + \cos^2 \theta)$
$\mathcal{T}_{0,0}(0, \Omega)$	$= \frac{1}{2} \sin^2 \theta$
$\mathcal{T}_{1,1}(0, \Omega)$	$= \frac{1}{4}(1 + \cos^2 \theta)$
$\mathcal{T}_{-1,0}(0, \Omega)$	$= -\frac{1}{2\sqrt{2}} \sin \theta \cos \theta e^{-i\chi}$
$\mathcal{T}_{-1,1}(0, \Omega)$	$= \frac{1}{4} \sin^2 \theta e^{-2i\chi}$
$\mathcal{T}_{0,1}(0, \Omega)$	$= \frac{1}{2\sqrt{2}} \sin \theta \cos \theta e^{-i\chi}$
$\mathcal{T}_{-1,-1}(1, \Omega)$	$= \frac{1}{4} \cos 2\gamma \sin^2 \theta$
$\mathcal{T}_{0,0}(1, \Omega)$	$= -\frac{1}{2} \cos 2\gamma \sin^2 \theta$
$\mathcal{T}_{1,1}(1, \Omega)$	$= \frac{1}{4} \cos 2\gamma \sin^2 \theta$
$\mathcal{T}_{-1,0}(1, \Omega)$	$= \frac{1}{2\sqrt{2}} (\cos 2\gamma \cos \theta - i \sin 2\gamma) \sin \theta e^{-i\chi}$
$\mathcal{T}_{-1,1}(1, \Omega)$	$= \frac{1}{4} (\cos 2\gamma (1 + \cos^2 \theta) - 2i \sin 2\gamma \cos \theta) e^{-2i\chi}$
$\mathcal{T}_{0,1}(1, \Omega)$	$= -\frac{1}{2\sqrt{2}} (\cos 2\gamma \cos \theta - i \sin 2\gamma) \sin \theta e^{-i\chi}$
$\mathcal{T}_{-1,-1}(2, \Omega)$	$= -\frac{1}{4} \sin 2\gamma \sin^2 \theta$
$\mathcal{T}_{0,0}(2, \Omega)$	$= \frac{1}{2} \sin 2\gamma \sin^2 \theta$
$\mathcal{T}_{1,1}(2, \Omega)$	$= -\frac{1}{4} \sin 2\gamma \sin^2 \theta$
$\mathcal{T}_{-1,0}(2, \Omega)$	$= -\frac{1}{2\sqrt{2}} (\sin 2\gamma \cos \theta + i \cos 2\gamma) \sin \theta e^{-i\chi}$
$\mathcal{T}_{-1,1}(2, \Omega)$	$= -\frac{1}{4} (\sin 2\gamma (1 + \cos^2 \theta) + 2i \cos 2\gamma \cos \theta) e^{-2i\chi}$
$\mathcal{T}_{0,1}(2, \Omega)$	$= \frac{1}{2\sqrt{2}} (\sin 2\gamma \cos \theta + i \cos 2\gamma) \sin \theta e^{-i\chi}$
$\mathcal{T}_{-1,-1}(3, \Omega)$	$= -\frac{1}{2} \cos \theta$
$\mathcal{T}_{0,0}(3, \Omega)$	$= 0$
$\mathcal{T}_{1,1}(3, \Omega)$	$= \frac{1}{2} \cos \theta$
$\mathcal{T}_{-1,0}(3, \Omega)$	$= \frac{1}{2\sqrt{2}} \sin \theta e^{-i\chi}$
$\mathcal{T}_{-1,1}(3, \Omega)$	$= 0$
$\mathcal{T}_{0,1}(3, \Omega)$	$= \frac{1}{2\sqrt{2}} \sin \theta e^{-i\chi}$

Table A.1: Expressions for the spherical tensor $\mathcal{T}_{qq'}(i, \Omega)$ for lines corresponding to magnetic dipole transitions (Landi & Landolfi 2004). It should be noted that $\mathcal{T}_{q'q}(i, \Omega) = \mathcal{T}_{qq'}(i, \Omega)^*$.

A.5 Wigner symbols

In this section, we give brief introduction into the Wigner 3- j , 6- j , and 9- j symbols and describe some basic properties of them. More detailed description of the symbols and theory connected with them can be found in Zare (1988), Varshalovich et al. (1989).

A.5.1 Wigner 3- j symbol

The Wigner 3- j symbol,

$$\begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix}, \quad (\text{A.20})$$

describes the coupling of two angular momenta in quantum mechanics. Here, j_1 , j_2 , and j_3 are the eigenvalues of the angular momentum operator, and m_1 , m_2 , and m_3 are the eigenvalues of their projections onto the quantization axis z , respectively. The 3- j symbol is related to the Clebsch-Gordan coefficients by

$$\begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix} = (-1)^{j_3+m_3+2j_1} \frac{1}{\sqrt{2j_3+1}} C_{j_1, -m_1, j_2, -m_2}^{j_3, m_3}, \quad (\text{A.21})$$

and inverse relation

$$C_{j_1, m_1, j_2, m_2}^{j_3, m_3} = (-1)^{j_1-j_2+m_3} \sqrt{2j_3+1} \begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & -m_3 \end{pmatrix}. \quad (\text{A.22})$$

A Clebsch-Gordan coefficient, $C_{j_1, m_1, j_2, m_2}^{j_3, m_3}$, represents the probability amplitude that j_1 and j_2 with their projections m_1 and m_2 are coupled into the resultant angular momentum j_3 with the projection m_3 .

The coefficients in the 3- j symbol satisfy the follow selection rules:

- $m_1 = -|j_1|, \dots, |j_1|$, $m_2 = -|j_2|, \dots, |j_2|$, and $m_3 = -|j_3|, \dots, |j_3|$.
- $m_1 + m_2 + m_3 = 0$.
- $|j_1 - j_2| \leq j_3 \leq (j_1 + j_2)$ (triangular inequality).
- $j_1 + j_2 + j_3$ is an integer.

If these conditions are not satisfied, then the 3- j symbol (A.20) is zero.

The 3- j symbols satisfy the orthogonality relations:

$$\sum_{m_1, m_2} \begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix} \begin{pmatrix} j_1 & j_2 & j_3' \\ m_1 & m_2 & m_3' \end{pmatrix} = (2j_3 + 1)^{-1} \delta_{j_3 j_3'} \delta_{m_3 m_3'}, \quad (\text{A.23})$$

$$\sum_{j_3, m_3} (2j_3 + 1) \begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix} \begin{pmatrix} j_1 & j_2 & j_3 \\ m_1' & m_2' & m_3 \end{pmatrix} = \delta_{m_1 m_1'} \delta_{m_2 m_2'}. \quad (\text{A.24})$$

An even permutation of the columns leaves the numerical value of the 3- j symbol unchanged,

$$\begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix} = \begin{pmatrix} j_2 & j_3 & j_1 \\ m_2 & m_3 & m_1 \end{pmatrix} = \begin{pmatrix} j_3 & j_1 & j_2 \\ m_3 & m_1 & m_2 \end{pmatrix}, \quad (\text{A.25})$$

while an odd permutation is equivalent to multiplication by $(-1)^{j_1+j_2+j_3}$. The replacement of the bottom row by the negative of all its arguments is also equivalent to multiplication by $(-1)^{j_1+j_2+j_3}$.

The 3- j symbol can be calculated by

$$\begin{aligned} \begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix} &= (-1)^{j_1-j_2-m_3} \Delta(j_1 j_2 j_3) \times \\ &\times \sqrt{(j_1+m_1)!(j_1-m_1)!(j_2+m_2)!(j_2-m_2)!(j_3+m_3)!(j_3-m_3)!} \times \\ &\times \sum_t \frac{(-1)^t}{f(t)}, \end{aligned} \quad (\text{A.26})$$

where the triangular coefficient, Δ , is

$$\Delta(abc) = \sqrt{\frac{(a+b-c)!(a-b+c)!(-a+b+c)!}{(a+b+c+1)!}}, \quad (\text{A.27})$$

and

$$\begin{aligned} f(t) &= t!(j_1+j_2-j_3-t)!(j_1-m_1-t)!(j_2+m_2-t)! \times \\ &\times (j_3-j_2+m_1+t)!(j_3-j_1-m_2+t)!. \end{aligned} \quad (\text{A.28})$$

The sum in (A.26) is over all integers t for which the factorials in $f(t)$ all have non-negative arguments.

A.5.2 Wigner 6- j symbol

Three angular momenta \mathbf{j}_1 , \mathbf{j}_2 , and \mathbf{j}_3 may be coupled to a resultant angular momentum \mathbf{j} in three ways:

1. $\mathbf{j}_1 + \mathbf{j}_2 = \mathbf{j}_{12}$, $\mathbf{j}_{12} + \mathbf{j}_3 = \mathbf{j}$;
2. $\mathbf{j}_2 + \mathbf{j}_3 = \mathbf{j}_{23}$, $\mathbf{j}_1 + \mathbf{j}_{23} = \mathbf{j}$;
3. $\mathbf{j}_1 + \mathbf{j}_3 = \mathbf{j}_{13}$, $\mathbf{j}_{13} + \mathbf{j}_2 = \mathbf{j}$.

The Wigner 6- j symbol,

$$\left\{ \begin{matrix} j_1 & j_2 & j_{12} \\ j_3 & j & j_{23} \end{matrix} \right\}, \quad (\text{A.29})$$

describes the coupling of three angular momenta and can be given through the Clebsch-Gordan coefficients:

$$\begin{aligned} &\sum C_{j_{12}, m_{12}, j_3, m_3}^{j, m} C_{j_1, m_1, j_2, m_2}^{j_{12}, m_{12}} C_{j_1, m_1, j_{23}, m_{23}}^{j', m'} C_{j_2, m_2, j_3, m_3}^{j_{23}, m_{23}} = \\ &= \delta_{jj'} \delta_{mm'} (-1)^{j_1+j_2+j_3+j} \sqrt{(2j_{12}+1)(2j_{23}+1)} \left\{ \begin{matrix} j_1 & j_2 & j_{12} \\ j_3 & j & j_{23} \end{matrix} \right\}. \end{aligned} \quad (\text{A.30})$$

Here the sum is over m_1 , m_2 , m_3 , m_{12} , and m_{23} , while m and m' are fixed. The symbol δ is a Kronecker delta-symbol.

The coefficients in the 6- j symbol (A.29) are either integers or half-integers. Their triads, (j_1, j_2, j_{12}) , (j_{23}, j_1, j) , (j_2, j_3, j_{23}) , and (j_{12}, j_3, j) , must satisfy the following conditions:

- Each triad satisfies the triangular inequality.
- The sum of the elements of each triad is an integer.

If these conditions are not satisfied, then the 6- j symbol (A.29) is zero.

The 6- j symbol is invariant under permutation of their columns and under interchange of the upper and lower elements in any two columns.

The 6- j symbol can be calculated using the Racah formula:

$$\left\{ \begin{array}{ccc} a & b & c \\ d & e & f \end{array} \right\} = \Delta(abc)\Delta(aef)\Delta(dbf)\Delta(dec) \times \sum_t \frac{(-1)^t(t+1)!}{f(t)}, \quad (\text{A.31})$$

where Δ is a triangle coefficient (A.27), and

$$f(t) = (t-a-b-c)!(t-a-e-f)!(t-d-b-f)!(t-d-e-c)! \times (a+b+d+e-t)!(b+c+e+f-t)!(a+c+d+f-t)!. \quad (\text{A.32})$$

The sum in (A.31) is over all integers t for which the factorials in $f(t)$ all have non-negative arguments.

A.5.3 Wigner 9- j symbol

Four angular momenta, j_1, j_2, j_3, j_4 , can be coupled to give a resultant angular momentum j in the ways:

1. $j_1 + j_2 = j_{12}, \quad j_3 + j_4 = j_{34}, \quad j_{12} + j_{34} = j;$
2. $j_1 + j_3 = j_{13}, \quad j_2 + j_4 = j_{24}, \quad j_{13} + j_{24} = j;$
3. $j_1 + j_4 = j_{14}, \quad j_2 + j_3 = j_{23}, \quad j_{14} + j_{23} = j.$

The Wigner 9- j symbol,

$$\left\{ \begin{array}{ccc} j_1 & j_3 & j_{13} \\ j_2 & j_4 & j_{24} \\ j_{12} & j_{34} & j \end{array} \right\}, \quad (\text{A.33})$$

is associated with the coefficients of unitary transformations which connect state vectors corresponding to different coupling schemes of four angular momenta, and can be defined through the 3- j symbols:

$$\begin{aligned} & \left\{ \begin{array}{ccc} j_1 & j_3 & j_{13} \\ j_2 & j_4 & j_{24} \\ j_{12} & j_{34} & j \end{array} \right\} = \\ & = \sum_{\text{All } m} \begin{pmatrix} j_1 & j_3 & j_{13} \\ m_1 & m_3 & m_{13} \end{pmatrix} \begin{pmatrix} j_2 & j_4 & j_{24} \\ m_2 & m_4 & m_{24} \end{pmatrix} \begin{pmatrix} j_{12} & j_{34} & j \\ m_{12} & m_{34} & m \end{pmatrix} \times \\ & \quad \times \begin{pmatrix} j_1 & j_2 & j_{12} \\ m_1 & m_2 & m_{12} \end{pmatrix} \begin{pmatrix} j_3 & j_4 & j_{34} \\ m_3 & m_4 & m_{34} \end{pmatrix} \begin{pmatrix} j_{13} & j_{24} & j \\ m_{13} & m_{24} & m \end{pmatrix}, \quad (\text{A.34}) \end{aligned}$$

where symbols m_i are the eigenvalues of the projections on the z -axis of the related angular momenta \hat{j}_i .

The $9-j$ symbol is invariant under an even permutation of rows or columns but is multiplied by $(-1)^{(j_1+j_2+j_3+j_4+j_{12}+j_{13}+j_{24}+j_{34}+j)}$, under an odd permutation of rows or columns, and under transposing operation.

A.6 List of analyzed reconstructions

Notation	Type of reconstruction	Regularization parameter, μ	Number of iterations
Z1	Reconstruction based on the Zeeman-effect data and optimized for the whole corona. The potential field approximation is used as an initial condition.	10^{-3}	47
Z2	Reconstruction based on the Zeeman-effect data and optimized for the perturbed region only. The potential field approximation is used as initial condition.	10^{-3}	99
H1	Reconstruction based on the Hanle-effect data and optimized for the whole corona. The potential field approximation is used as initial condition.	10^{-5}	7
H2	Reconstruction based on the Hanle-effect data and optimized for the perturbed region only. The potential field approximation is used as initial condition.	10^{-5}	20
H3	Reconstruction based on the Hanle-effect data and optimized for the perturbed region only. The potential field approximation is used as initial condition.	10^{-5}	59
ZH1	Reconstruction based on the Hanle-effect data and optimized for the whole corona. The Z1-solution is used as initial condition.	10^{-5}	5
ZH2	Reconstruction based on the Hanle-effect data and optimized for the perturbed region only. The Z1-solution is used as initial condition.	10^{-5}	13
ZH3	Reconstruction based on the Hanle-effect data and optimized for the perturbed region only. The Z1-solution is used as initial condition.	10^{-5}	30

Table A.2: Notations for the performed reconstructions

A.7 Cross sections of the reconstructed field

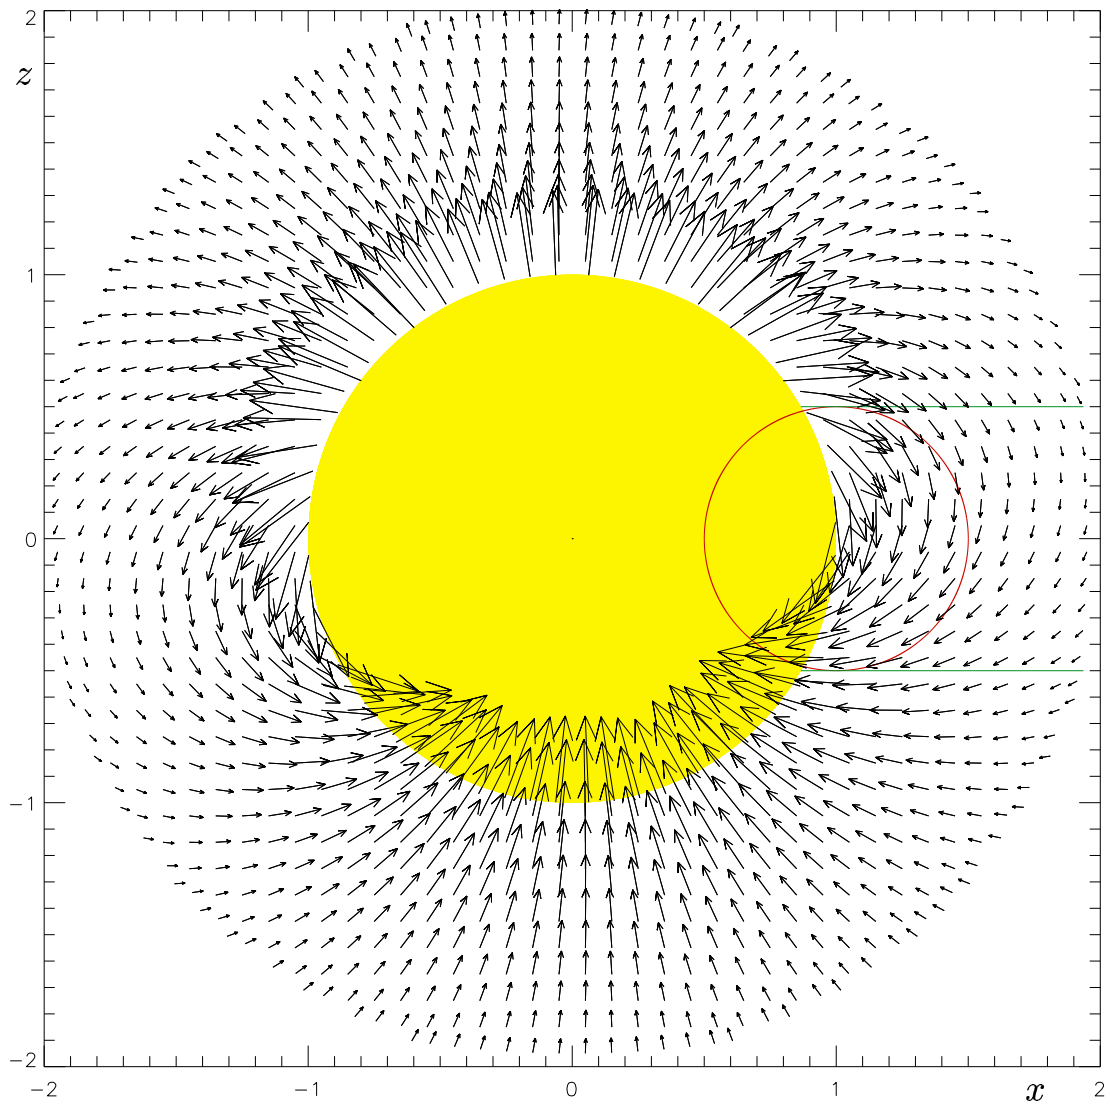

Figure A.2: (a) The model field configuration: the cross section defined by the $y = -0.05R_{\odot}$ plane. The red circle represents the projection of the perturbing circular current on the section plane. It should be noted that the current lies in the plane $y = 0$. The green horizontal lines bound the analyzed perturbed region.

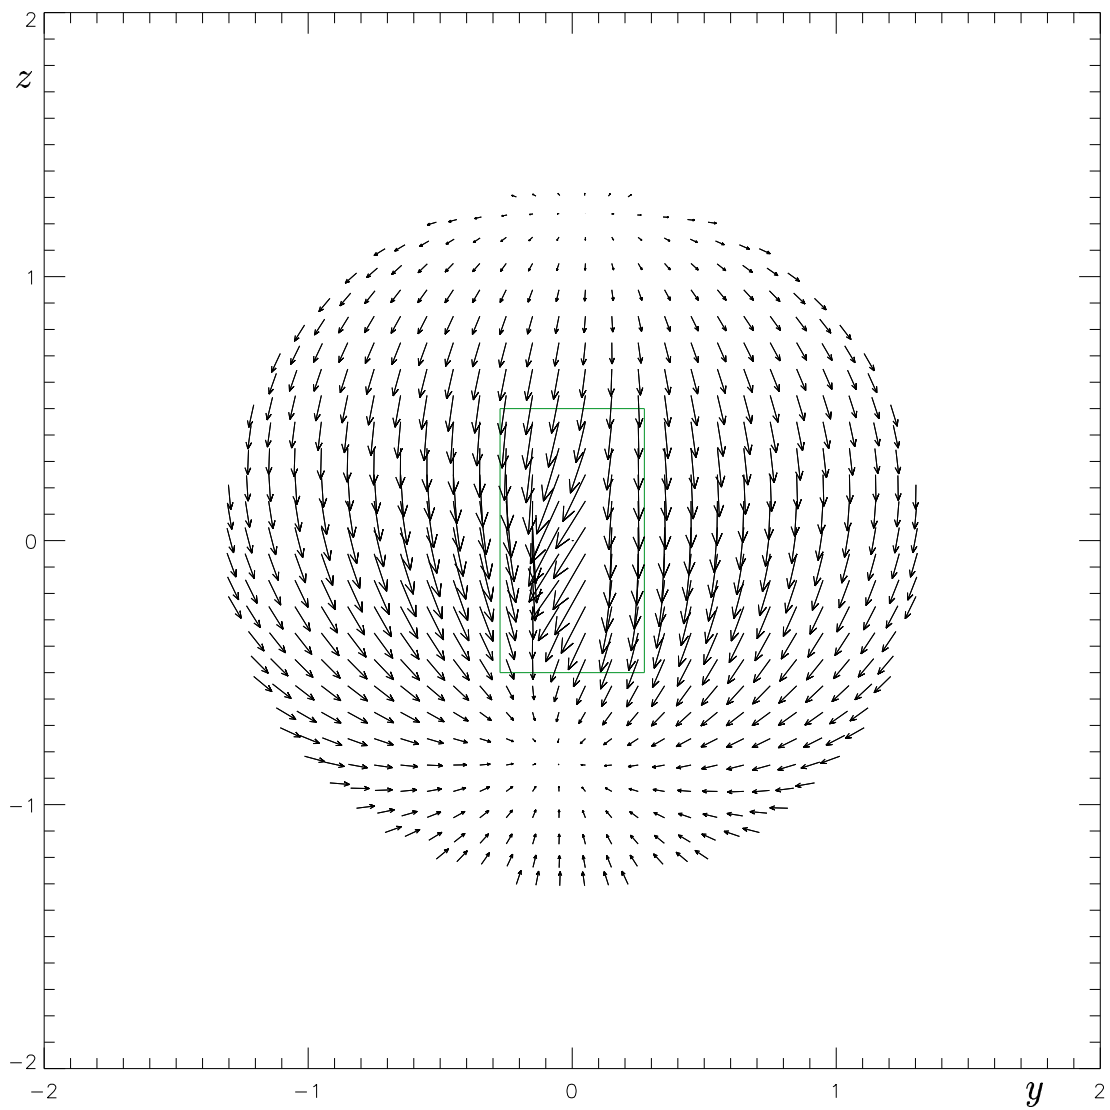

Figure A.2: (b) The model field configuration: the cross section defined by the $x = 1.55R_{\odot}$ plane. The green box bounds the analyzed perturbed region.

Figure A.2: The model field configuration: the cross section defined by the $z = 0.15R_{\odot}$ plane. The two green lines bound the analyzed perturbed region.

Figure A.3: (a) The potential field reconstruction: the cross section defined by the $y = -0.05R_{\odot}$ plane.

Figure A.3: (b) The potential field reconstruction: the cross section defined by the $x = 1.55R_{\odot}$ plane.

Figure A.3: The potential field reconstruction: the cross section defined by the $z = 0.15R_{\odot}$ plane.

Figure A.4: (a) The Zeeman-effect reconstruction for $\mu = 10^{-3}$ after 47 iteration (Z1): the cross section defined by the $y = -0.05R_{\odot}$ plane.

Figure A.4: (b) The Zeeman-effect reconstruction for $\mu = 10^{-3}$ after 47 iteration (Z1): the cross section defined by the $x = 1.55R_{\odot}$ plane.

Figure A.4: (c) The Zeeman-effect reconstruction for $\mu = 10^{-3}$ after 47 iteration (Z1): the cross section defined by the $z = 0.15R_{\odot}$ plane.

Figure A.5: (a) The Zeeman-effect reconstruction for $\mu = 10^{-3}$ after 99 iteration (Z2): the cross section defined by the $y = -0.05R_{\odot}$ plane.

Figure A.5: (b) The Zeeman-effect reconstruction for $\mu = 10^{-3}$ after 99 iteration (Z2): the cross section defined by the $x = 1.55R_{\odot}$ plane.

Figure A.5: (c) The Zeeman-effect reconstruction for $\mu = 10^{-3}$ after 99 iteration (Z2): the cross section defined by the $z = 0.15R_{\odot}$ plane.

Figure A.6: (c) The Hanle-effect reconstruction for $\mu = 10^{-5}$ after 7 iteration (H1): the cross section defined by the $y = -0.05R_{\odot}$ plane.

Figure A.6: (b) The Hanle-effect reconstruction for $\mu = 10^{-5}$ after 7 iteration (H1): the cross section defined by the $x = 1.55R_{\odot}$ plane.

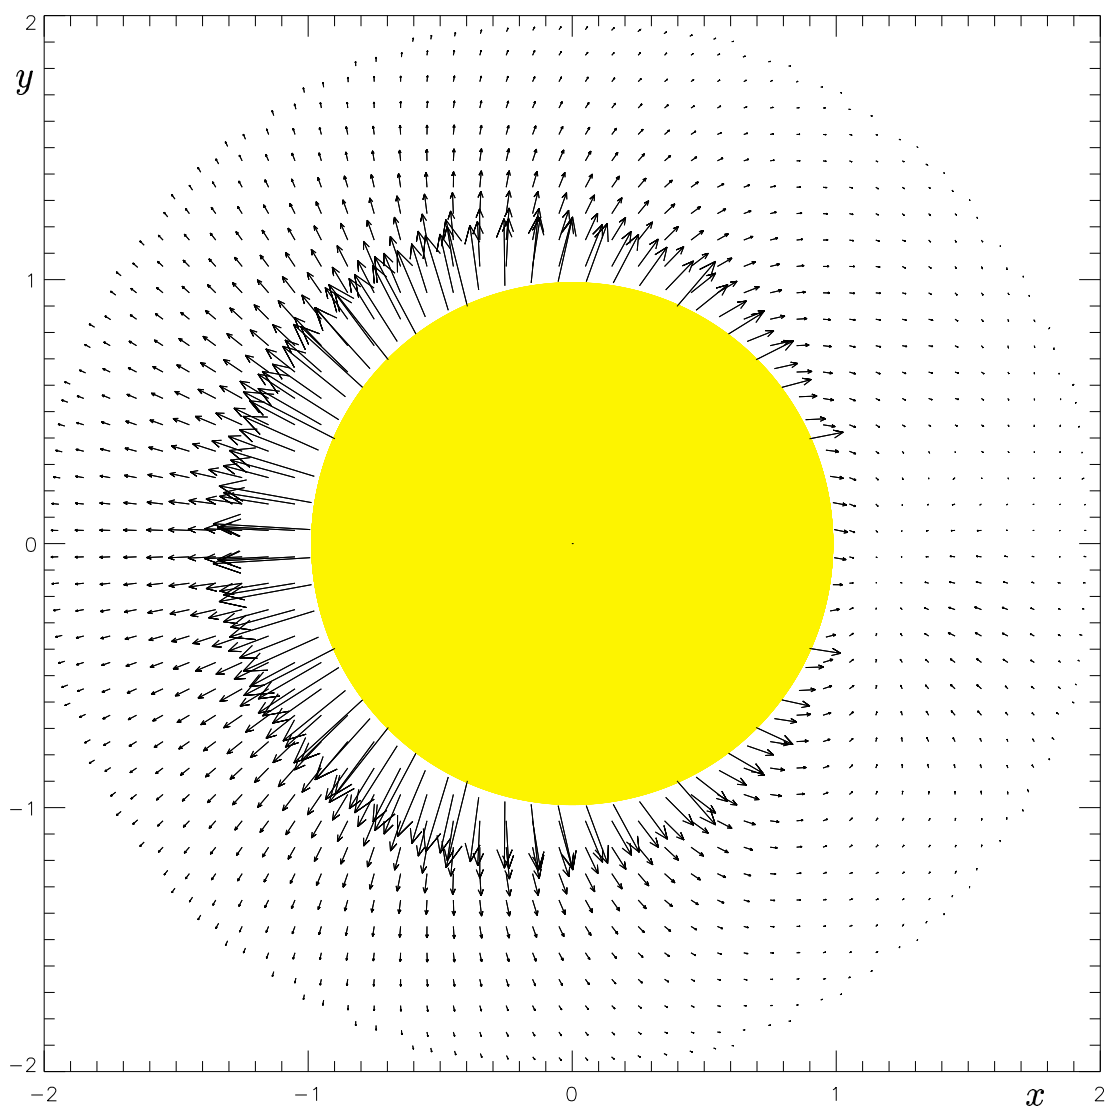

Figure A.6: (c) The Hanle-effect reconstruction for $\mu = 10^{-5}$ after 7 iteration (H1): the cross section defined by the $z = 0.15R_{\odot}$ plane.

Figure A.7: (a) The Hanle-effect reconstruction for $\mu = 10^{-5}$ after 20 iteration (H2): the cross section defined by the $y = -0.05R_{\odot}$ plane.

Figure A.7: (b) The Hanle-effect reconstruction for $\mu = 10^{-5}$ after 20 iteration (H2): the cross section defined by the $x = 1.55R_{\odot}$ plane.

Figure A.7: (c) The Hanle-effect reconstruction for $\mu = 10^{-5}$ after 20 iteration (H2): the cross section defined by the $z = 0.15R_{\odot}$ plane.

Figure A.8: (a) The Hanle-effect reconstruction for $\mu = 10^{-5}$ after 59 iteration (H3): the cross section defined by the $y = -0.05R_{\odot}$ plane.

Figure A.8: (b) The Hanle-effect reconstruction for $\mu = 10^{-5}$ after 59 iteration (H3): the cross section defined by the $x = 1.55R_{\odot}$ plane.

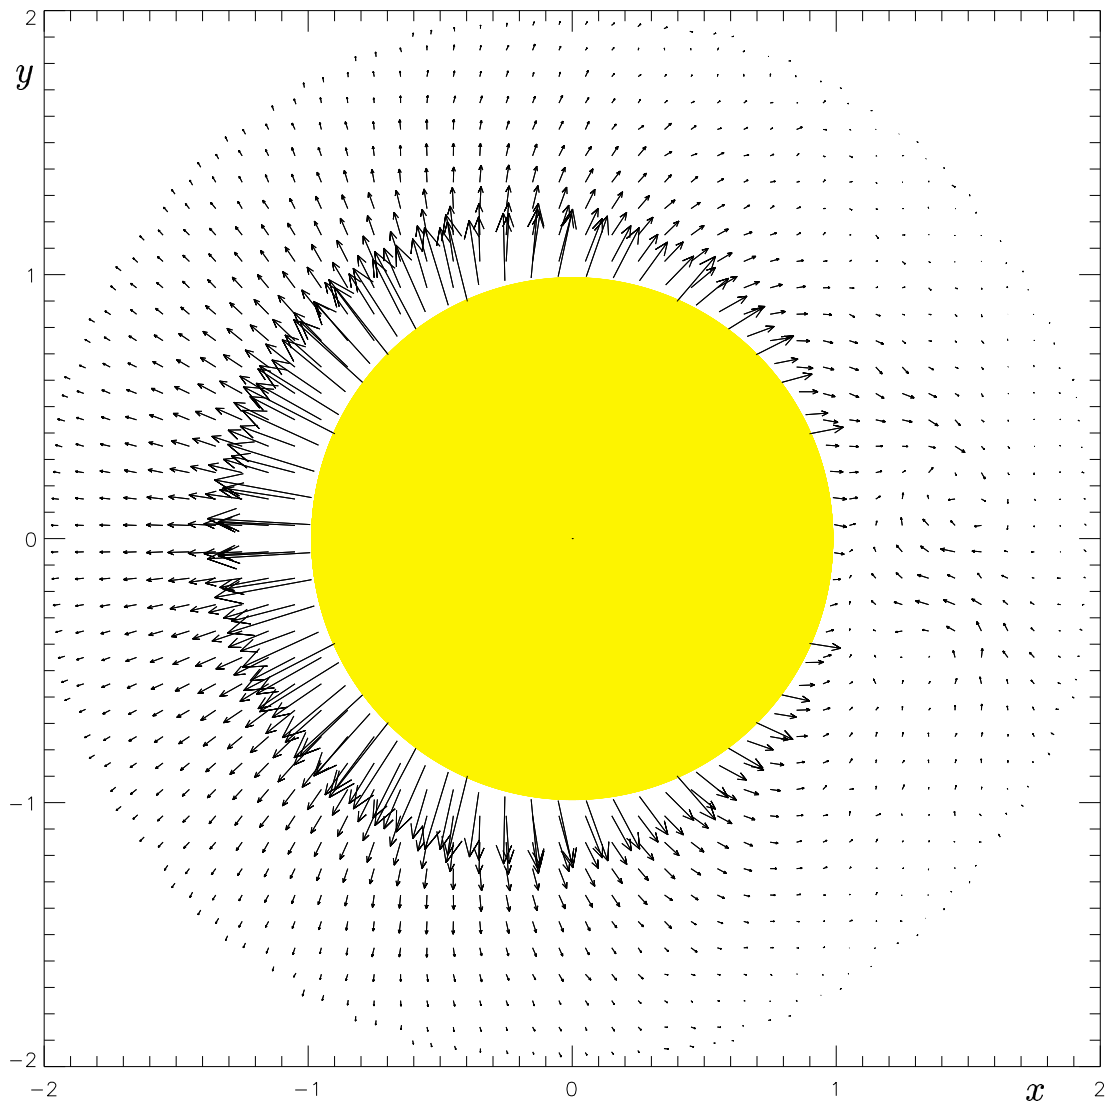

Figure A.8: (c) The Hanle-effect reconstruction for $\mu = 10^{-5}$ after 59 iteration (H3): the cross section defined by the $z = 0.15R_{\odot}$ plane.

Figure A.9: (a) The Hanle-effect reconstruction for $\mu = 10^{-5}$ after 13 iterations (ZH2). Here the Zeeman-effect solution Z1 depicted in the Figs. A.4 was used as initial field in the iterations. It is shown the cross section defined by the $y = -0.05R_{\odot}$ plane.

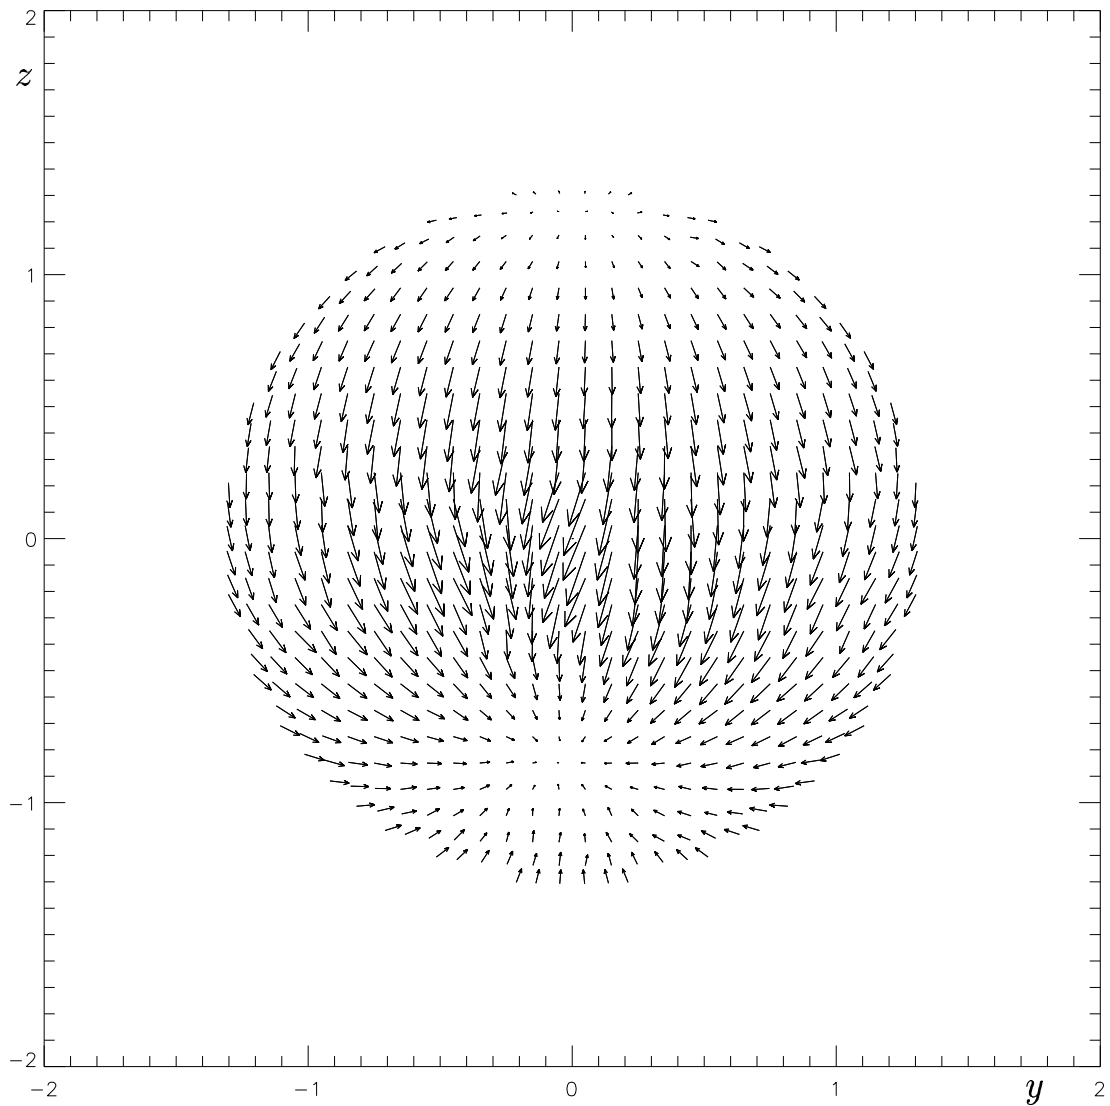

Figure A.9: (b) The Hanle-effect reconstruction for $\mu = 10^{-5}$ after 13 iterations (ZH2). Here the Zeeman-effect solution Z1 depicted in the Figs. A.4 was used as initial field in the iterations. It is shown the cross section defined by the $x = 1.55R_{\odot}$ plane.

Figure A.9: (c) The Hanle-effect reconstruction for $\mu = 10^{-5}$ after 13 iterations (ZH2). Here the Zeeman-effect solution Z1 depicted in the Figs. A.4 was used as initial field in the iterations. It is shown the cross section defined by the $z = 0.15R_{\odot}$ plane.

Acknowledgements

The presented work was performed in the Max-Planck Institute for Solar System Research and was supported by the International Max-Planck Research School on Physical Processes in the Solar System and Beyond at the Universities of Braunschweig and Göttingen. I thank Dr. D. Schmitt, the coordinator of the school, for the organization in the school. Also, I thank him and the Institute's administration staff for the possibility to avoid a much of bureaucracy work.

I am very grateful to Dr. B. Inhester, who proposed the topic for the thesis, for the guidance and helpful discussions during the work. I also thank Dr. T. Wiegmann and Dr. N.-E. Raouafi for the helpful discussions.

Many thanks to Prof. F. Kneer and Prof. E. Marsch for careful reading the thesis and useful remarks.

Thanks to Prof. R. Schwenn and Prof. E. Marsch for the organizing the coronal physics seminars that supported for better understanding of the present state of this branch of physics. Also I thank Prof. F. Kneer for the seminars in solar physics at the Goettingen observatory.

I thank E. A. Jensen for providing me with the information about Cassini's passage beyond the corona.

I also thank my friends and colleagues at MPS for the interesting discussions and nice time we spent together.

Curriculum Vitae

- Geburt: Am 5.4.1974 in Ruba, Kreis Witebsk, Weißrussland (Belarus)
- Eltern: Ivan Kramar
Stepanija Kramar, geb. Dodyk
- Staats-
bürgerschaft: Weißrussisch (Belarus)
- Schulbildung: 9/1981 bis 7/1991 Schule N28 (Grundschule und Gymnasium), Witebsk
- Studium 9/1991 bis 7/1996 Physikstudium an der Physikalischen Fakultät der Staatsuniversität Witebsk.
Diplomarbeit: "The dielectrical properties of the $\text{PbAl}_{1/2}\text{Nb}_{1/2}\text{O}_3 - \text{PbIn}_{1/2}\text{Nb}_{1/2}\text{O}_3$ solid solutions"
- 10/1997 bis 2/2002 Wissenschaftlicher Mitarbeiter des Instituts für Physik der Nationalen Akademie der Wissenschaften von Weißrussland, Minsk
- 2/2002 bis 3/2005 Doktorarbeit am Max-Planck-Institut für Sonnensystemforschung (früher Aeronomie), Katlenburg-Lindau, und der Universitäts-Sternwarte, Göttingen
